

AGENDA OF THE PROTECTION AND POLICY COMMITTEE

**THURSDAY, NOVEMBER 19, 2020, 5:30 PM
CONTINUED MEETING**

The Protection & Policy Committee Meeting from October 8, 2020 was recessed at 9:37 p.m. The meeting will reconvene at 5:30 p.m. on November 19, 2020.

**This is a virtual meeting.
Please see the zoom instructions in the agenda.**

A. Zoom Meeting Information.

- I. This item contains instructions and information for the Zoom virtual meeting.

B. Roll Call.

C. Approval of the Agenda.

D. Regular Business.

- I. Consideration with possible action on a request by Ald. Galvin, filed on behalf of constituent Brenda Staudenmaier, that the City consider taking fluoride out of the treatment process for the City water.

E. Adjournment.

- 1) THIS MEETING IS RECORDED: THE VIDEO OF THIS MEETING AND MINUTES ARE AVAILABLE ONLINE AT www.greenbaywi.gov
- 2) ACCESSIBILITY: Any person wishing to attend who requires special accommodation because of a disability, should contact the City Safety Manager at 920-448-3125 at least 48 hours before the scheduled meeting time so that arrangements can be made.

- 3) **QUORUM:** Please take notice that a majority or quorum of the Common Council will attend this Protection and Policy committee meeting and will constitute a meeting of the Common Council for purposes of discussion and information gathering relative to this agenda.
- 4) **REPRESENTATION:** The party requesting the communication, or their representative, should be present at this meeting.
- 5) **FOR ALL LICENSING ISSUES,** the Committee may convene in closed session pursuant to §19.85 (1)(b) and/or §19.85 (1)(f) Wis. Stats., for the purpose of considering information with respect to licensing for a person, including financial, social, or personal information. The Committee will thereafter reconvene in open session pursuant to Section 19.85(2), Wis. Stats., to take action on items discussed in closed session, if appropriate, and to consider the remainder of the agenda.

Additional Information

1. Wisconsin Open Meetings Law still applies
 - a. Persons interested in speaking to an item must give their name and address
 - b. Committee/Commission/Board members will still follow *Roberts Rules of Order*
2. All zoom meetings will have a password in the instructions. Please enter when prompted.
3. Please log into the Zoom meeting 10 minutes before the meeting starts to ensure proper technology is working.
 - a. If you are a Board Member, please log into [CivicClerk](#) with a computer, laptop, or tablet device.
4. Once you are in the meeting please mute yourselves.
 - a. You may unmute yourself when you are called upon to speak.
5. Waiting room
 - a. When you call in, all callers/participants will be placed in a “waiting room.”
 - b. Persons on the agenda will be admitted to the meeting, and then once the item is concluded, the host will permanently mute you from the meeting (you can still hear the meeting).
6. Using Zoom with a tablet or computer
 - a. Tablet—you will be asked to sign in. Download the app either with the Apple Store or the Play Store
 - b. Computer—you will be asked to sign in. You may download the app or click on the link to open Zoom in your browser.
7. Registering
 - a. The host may ask you to register for the meeting. A registration link will be sent to you along with the invite. You’ll receive another email confirming that you’re registered for the meeting.
 - b. If you’re using a phone, your registration will still be tied to an email.
8. Raising your hand
 - a. Committee members—you can either use CivicClerk and request to speak or you can “raise your hand” in the zoom meeting (you’d need to use a computer or tablet) to let the host know you’d like to speak. You can also un-mute yourselves and start speaking.
 - b. Persons on the agenda—you can “raise your hand” but you’d need to use a computer. You will be allowed to speak, per Wisconsin Open Meetings Rules, once the committee has “opened the floor for interested parties to speak.” Once the committee is finished with your agenda item, the host will mute you permanently, unless the committee opens the floor again.
9. What devices should I use?
 - a. Smart phone (please see more detailed instructions on page 3)
 - b. Land line
 - c. Tablet—well in advance of the meeting, please download the Zoom Meeting app before you join a meeting by using either the Apple Store or the Play Store. You will be asked to input your name, thus identifying you for the meeting. You’ll also be asked to verify your email.
 - d. Computer—well in advance of the meeting, please download the Zoom Meeting app, but you can also click on a link to open the Zoom Meeting in your browser. You will be asked to input your name, thus identifying you for the meeting.
 - e. For tablet and computer users—if you download the app you will be asked to verify your email.
10. Zoom etiquette
 - a. Muting yourselves when you’re not talking will prevent your background noise from interfering with others’ ability to listen to and participate in the meeting.
 - b. If you’re using a telephone, please identify yourself with your phone number and name before you speak. Zoom meeting hosts can see only your telephone number and will ask you to identify yourselves.
11. Closed session
 - a. Persons in the Zoom meeting will be put into a waiting room while the committee meets in Closed Session. Participants will be admitted back into the Zoom meeting once the committee reconvenes in Open Session.
 - b. Persons watching live on YouTube will see a gray screen with the City logo during closed session.
12. Persons interested in attending anonymously or listening to the meeting may call in by dialing *67 followed by the phone number above.

Calling into the Zoom meeting using a smartphone

1. Dial the phone number listed at the beginning of this document.
2. When prompted, enter the Meeting ID number followed by #
 - a. If you're using a smartphone, you can access the keypad by clicking "Keypad" on your screen

3. Once you are in the meeting, notify the meeting host that you are in and state your name.
4. If you do not need to talk, please make sure your phone is on **Mute**
 - a. If you're using a smartphone, look at your screen and click the Mute button

- b. If you're using a computer, you should see a Mute button in the Zoom application

Members of the Green Bay Protection and Policy Committee:

On behalf of the Academy of General Dentistry (AGD) and its over 40,000 members, including more than 600 that make up the Wisconsin AGD (WIAGD), I am writing to express our strong support of community water fluoridation (CWF).

The AGD was founded in 1952 and has grown to be the second largest dental association, proudly working to address the most pressing issues that face general dentistry. General dentists are the primary oral health care providers for patients of all ages, and take responsibility for the diagnosis, treatment, and coordination of services to meet patients' oral health needs. Approximately 82% of Wisconsin's licensed dentists are general dentists.

We work diligently to advocate for effective policies that will most benefit the oral health care of patients and the public. Among our top priorities is increasing access to oral health care in every community, which cannot be solved by any one silver bullet, but is a multipronged approach. Many barriers to oral health care are complex and timely in terms of identifying effective and equitable solutions. However, CWF is one of the single most effective ways proven to prevent dental caries (cavities) and accessible to every single community member regardless of other barriers to care they may face.

Through 75 years of practice and decades of research, CWF is proven to be effective and safe in reducing dental caries in both children and adults. The evidence surrounding CWF is why the Center for Disease Control and Prevention (CDC) named it one of [ten great public health achievements of the 20th century](#). Nearly all credible health organizations recognize CWF's efficacy alongside the CDC, despite the many attempts by opponents to discredit and denounce it.

Several studies have demonstrated how the removal of fluoridation from public water supplies can negatively impact members of that community. [BMC Oral Health published a peer-reviewed research article](#) that compared average caries-related procedures and treatment costs in Juneau, Alaska, before and after discontinuing their CWF. Results showed the study population in 2003, during optimal CWF, was 25.2% less likely to receive dental caries procedures than in 2012, almost six years post-CWF cessation. The difference between children seven years and younger was significantly greater than that of the entire study population.

It is most important to note that results were based off Medicaid dental claim records from Medicaid-eligible residents of Juneau. This data represents children and adolescents whose family's income is no more than 150-200% of the Federal Poverty Level: one of the most vulnerable populations in today's society. This does not even touch on adults, who States are not required to provide any oral health benefit to under their Medicaid program. This does not touch on how COVID-19 and the current state of

our nation has created additional barriers. Finally, this does not touch on the wide range of residents who may have been benefitting from CWF but simply didn't fall into this study's population.

With optimal levels of water fluoridation, all members of the Green Bay community, and the four communities who purchase their water from Green Bay, have the opportunity to protect their teeth regardless of age, race, income or barriers to oral health care. We respectfully urge the Committee and City of Green Bay to continue fluoridating its public water system. We ask that you stand with us in protecting the oral health of your community.

Thank you for allowing the AGD to express our support of CWF and we appreciate your consideration in advance. If you have any questions, please contact our Government Relations staff at ninia.linero@agd.org.

Green Bay, WI 54305**

Re: Potable Drinking Water -- Fluoride Addition

Dear Nancy:

Thank you for the opportunity to discuss the topic of fluoride addition in potable drinking water. From time to time, questions come forth as to the viability of adding fluoride to public drinking water and its effectiveness in providing a measurable impact on the teeth of those drinking the water. When questions of this nature come forth, we show them the respect they are due by turning to the experts in the professions who see the end results on a daily basis. In this case, our dental professionals are the front-line viewers of what the addition of fluoride to public drinking water has on the teeth of those who drink water with versus without the addition. From our local dentists to the American Dental Association, the results, and recommendations they consistently urge is to maintain a beneficial level of fluoride in drinking so as to aid in the development and protection of teeth. The Green Bay Water Utility has followed CDC and WDNR guidelines for decades in the addition of fluoride to its drinking water to the benefit of many generations of families. In following the recommendations and results from the experts in the dental professions, as well as the national associations within that field, we continue to support the fluoride addition to potable drinking water.

Thank you very much for your time.

Sincerely,

**Douglas J. Martin, P.E.
Director of Public Works**

**SCOTT MUNICIPALITY UTILITY - BROWN COUNTY WISCONSIN
RESOLUTION 2020-08-01
SAFE DRINKING WATER**

WHEREAS, Scott Municipal Utility's (SMU's) number one objective is to provide customers with safe drinking water, and

WHEREAS, SMU strives to follow all federal, Wisconsin, and local regulatory guidelines and recommendations relative to the addition of and maintenance of recommended chemicals, including fluoride, and

WHEREAS, SMU, at the same time, recognizes the concerns of customers relative to save levels of said chemicals in their drinking water, and

WHEREAS, SMU will continue to depend on the medical experts, scientific community, and regulatory agencies to establish the safe level for each chemical found in or added to the drinking water provided to our customers, and

WHEREAS, SMU is a wholesale customer of the Green Bay Water Utility.

NOW THEREFORE BE IT RESOLVED the SMU strongly encourages the Green Bay Water Utility to follow all federal, Wisconsin, and local regulatory guidelines and recommendations relative to the addition of and maintenance of recommended chemicals, including fluoride, and

FURTHER, SMU strongly encourages Green Bay Water Utility to depend on the medical experts, scientific community, and regulatory agencies to establish the safe level for each chemical found in or added to the drinking water provided to their wholesale and retail customers.

Adopted this 3rd day of August, 2020.

I hereby certify that the foregoing resolution was duly adopted by the Scott Municipal Utility Commission at a legal meeting on the 3rd day of August, 2020.

ADOPTED THIS 3rd DAY OF AUGUST, 2020

RE: Green Bay Water Utility Fluoride Levels

August 11, 2020

The Village of Hobart, purchasing water from Green Bay Water Utility for about a decade, has been very satisfied with the quality of the water and levels of Fluoride in that water.

It has been our experience that Green Bay Water Utility, being a member of the AWWA, keeps current with the applicable research and recommendations for optimal Fluoride levels in the drinking water. The recommendations of AWWA in turn follow the science and research conducted by the CDC, AMA, and WHO among others, for beneficial and safe levels of Fluoride in our drinking water.

The proven benefits from Fluoride to aid in strengthening teeth and preventing tooth decay has been well documented worldwide as nearly all developed countries practice fluoridation. The 25% reduction in tooth decay estimated from the use of low levels of fluoride is a safe and cost effective means of aiding our residents in maintaining a healthy lifestyle while potentially saving money in health care costs.

The Village of Hobart does not wish to see a deviation in levels of Fluoride in our water supply from the Green Bay Water Utility. I believe changes from the AWWA recommended levels they have followed in the past will decrease the value of the water supplied to our residents.

Respectfully,

Jerry Lancelle
Public Works Director
Village of Hobart
920-655-3719

8/14//2020

Dear Green Bay Common Council,

On behalf of the Village of Wrightstown, I write to express our overwhelming support for community water fluoridation. The Green Bay Water Utility supplies us with treated water that contains fluoride at the appropriate level to promote dental health for our customers, and we would like to be able to continue this offering as a wholesale customer of the Green Bay Water Utility.

The science behind fluoridation of water and decades of success, with agreement from every major health organization from the Centers for Disease Control and Prevention (CDC) to the American Dental Association (ADA), concluded that fluoridated water protects teeth without posing risks to health. While fluoride is naturally occurring in almost all water supplies, we appreciate that Green Bay Water Utility has adjusted the level by adding fluoride to achieve the right amount to reduce tooth decay.

Before the common practice of fluoridation, health organizations believe lack of fluoride is one of the major reasons that many people needed dentures, which were quite common before widespread fluoridation. Science and studies prove that dental costs are lower and oral health problems have declined in fluoridated communities, having an important impact on our overall health and lowered many families' dental budgets.

Many times misleading information associates fluoride with fertilizer and industrial waste. The reality is that fluoride is extracted from phosphate rock, and so is phosphoric acid, an ingredient in name brand soft drinks such as Pepsi and Coca Cola. Neither one of them comes from fertilizer. It is important to base decision-making on true and corresponding health related information and the science behind water treatment.

Dental disease is the most common childhood disease and is associated with diabetes, adverse pregnancy outcomes, heart disease and lost school and work hours.

Science and health stats show fluoridated water decreases tooth decay by nearly 25 percent in children as well as in adults. The science behind this treatment has also proven to save communities money, by reducing costs and lost work hours spent on repairing tooth decay. For most communities, every \$1 invested in water fluoridation saves \$38 in unnecessary dental treatment costs. Green Bay Water Utility has been wise to use this proven intervention and we urge its continuation to benefit all of the people who drink Green Bay water.

Travis Coenen, Village Administrator

July 20th, 2020

To Whom it May Concern:

When my aunt asked me to write a statement regarding my perspective on community water fluoridation, I got excited. Not because writing a public health statement is what I want to do with my one hour of free time each night after I get my two kids to bed. Rather, I got excited to offer a very human perspective on the subject. I want to offer two distinct perspectives: a dentist and a father of two young children.

The first perspective I want to present is my professional take on the subject matter. I am a general dentist who sees many children in my practice in Madison, Wisconsin. What I know to be true is that dental decay in our pediatric population is an epidemic. According to peer-reviewed published articles, over 60% of our children in the United States experience dental decay by age five. By age 17, the percentage increases to 78 percent. The reality of this situation is that 60% of our under-five population is receiving multiple fillings/crowns/extractions. Of these patients, some handle it well in an out-patient setting while others are treated in the hospital under general anesthesia. This is the reality of the disease. I spend approximately 15% of my time doing fillings, extractions and crowns on these under-five patients. This is just the pediatric population. The adult population numbers get even worse.

Fluoride is not a cure-all for this problem. However, it has been demonstrated that community water fluoridation can reduce the rate of decay from 15-50% depending on the specific source you are citing. This means that we need to perform 15-50% less dental surgery on our under-five population. This may seem insignificant, but I would challenge you to face the reality that our system cannot handle a 15-50% increase in treatment for this population. We also cannot handle a 25-35% increase in necessary treatment for adult dental disease. The bottom line is that community water fluoridation is the most cost-effective way to manage dental decay. It is not the only way, but it is the most cost-effective way to combat this epidemic. It reaches everyone in Green Bay by simply turning on the faucet.

The second perspective I want to offer is that of a father. I have two children. One is age two and the other is two months old. My children eat organic, healthy foods (at least the two year-old). They also drink tap water that is fluoridated at the appropriate level of 0.7ppm. I choose to give them this water because I have yet to find a legitimate scientific study that demonstrates any negative health effects of fluoride levels of 0.7 ppm in our drinking water. The overwhelming preponderance of epidemiological studies that we have demonstrates no elevated levels of any systemic diseases linked to community water fluoridation at the level of 0.7ppm. Over 75 years of fluoridation in the U.S. and over 6,000

studies and research papers published have shown that fluoridation is effective at reducing decay for everyone and causes no adverse health effects in anyone. If that ever changes, I will be the first to change my tune. Until then, my children will benefit from the decay prevention provided by this public health measure. The alternative to this simple, preventive measure is too real for me. Earlier today, I struggled to treat two cavities on a 5-year-old girl. Ultimately, she would not allow me to treat the two cavities and we referred her to a pediatric specialist. I fear the she will not cooperate with them and require a trip to the hospital under general anesthesia to treat these cavities. This is, unfortunately, a weekly occurrence at our office. I am not in favor of ceasing fluoridation of our water and making these experiences a daily occurrence.

Prevention of disease is always the best practice. Treating a preventable disease is not going to rid us of this any disease. COVID-19 is a prime example that we are all facing right now. If we had a vaccination immediately available for COVID-19, the world would be immeasurably better. Water fluoridation is the closest thing that we have to a vaccination for dental cavities.

For the good of all of your families, please keep water fluoridation in place.

Re: Community water fluoridation

To whom it may concern,

Community water fluoridation is one of the most cost-effective and safe ways to improve oral health throughout a population. It has been in use since 1945 and has an incredibly long track record of success in reducing the caries rate of a population. Additionally, controlled water fluoridation has not been associated with any systemic health issues outside of fluorosis in a few uncontrolled cases. Finally, there have been a number of systematic reviews evaluating the cost-effectiveness of community fluoridation and they have all come to the same conclusion: it saves money.

There is unequivocal evidence supporting the efficacy, safety, and cost-efficiency of community water fluoridation. There is no substantiated evidence to the contrary. While I do not envy the political role of sorting through all of the misinformation provided by a vocal minority, I do feel that this debate was scientifically settled years ago.

I have included citations for you if you would like to review some of the evidence. Please let me know if you would like any additional information.

Re: Advocacy for Community Water Fluoridation

Dear Protection & Policy Committee and Green Bay City Council:

As your office considers Green Bay's budget, the Wisconsin Dental Association urges you to maintain support for community water fluoridation, which is one of the most equitable and impactful public health programs available today.

The COVID-19 pandemic has led communities across the country to appreciate the value of having a strong public health infrastructure. Dental offices have implemented new workflows and processes to keep patients, staff and themselves safe and healthy. All these measures have been in the name of health, but also come with unexpected costs to our public health budgets. The Wisconsin Dental Association understands that public health budgets have been under additional scrutiny since COVID-19 has impacted allocations of public health dollars. As these budgets are given a closer look, one of the most equitable and impactful public health programs is at risk in countless communities: community water fluoridation.

This is an issue that will directly impact the oral health in Green Bay. Community water fluoridation's power to prevent dental caries (the disease that causes cavities) is well worth the state's continued investment in public health. Because of the increased hesitancy by many Wisconsinites concerned about COVID-19 to access medical and dental providers, community water fluoridation may be one of the only preventive oral health measures they have access to in these uncertain times.

The economic benefits of community water fluoridation are also clear. The average cost per year for U.S. communities to fluoridate the water ranges from 50 cents per person for large communities to \$3.00 per person for small communities. The latest studies continue to demonstrate water fluoridation is effective in reducing dental decay by at least 25% in children and adults, including older adults. This remains true even when fluoride is widely available from other sources, such as fluoride toothpaste. Community water fluoridation is foundational in maintaining Wisconsin's oral health. According to the Centers for Disease Control and Prevention, (<https://www.cdc.gov/oralhealth/fast-facts/community-water-fluoridation/index.html>) communities of 1,000 or more see an average estimated return on investment of \$20 for every \$1 spent on water fluoridation. In addition, Communities served by fluoridated water save an average of \$32 per person a year by avoiding treatment for cavities.

Advocate...Educate...Empower...Serve

For more information on this issue, please reference tools at ada.org/fluoride and the 2018 "Fluoridation Facts" book (<https://www.ada.org/en/public-programs/advocating-for-the-public/fluoride-and-fluoridation/fluoridation-facts>).

We recognize that you will be considering many budget obligations in the near future. Community water fluoridation is the best low-cost, high-impact way for you to maintain optimal oral health in our communities. We urge you to fully fund community water fluoridation in any upcoming budget considerations.

Regards,

September 18, 2020

Green Bay Protection and Welfare Committee,

We, the appointed Board of Health, wish to submit this letter in support of continued fluoridation of our local water. We understand that this topic has again been brought forward for consideration.

At our August 11, 2020 meeting, two constituents spoke against fluoridation and were supported by two individuals calling from other states identifying as experts. Water fluoridation was supported and evidence was cited by Dr. Russell Dunkel, State Dental Director as well as an outside caller, Dr. Johnny Johnson. Nancy Quirk, Green Bay Water Utility General Manager, with expertise in water safety gave reassurance of the support and evidence of benefit to fluoridation. We are grateful for the interested participation of our community on this and all topics and are committed to examining credible new data and research as it becomes available.

According to the Center for Disease Control website (CDC.gov), community water fluoridation is recommended by nearly all public health, medical, and dental organizations. It is recommended by the American Dental Association, American Academy of Pediatrics, US Public Health Service, and World Health Organization. The CDC goes on to say that because of its contribution to the large decline in cavities in the United States since the 1960s, CDC named community water fluoridation one of 10 great public health achievements of the 20th century.

With this firm endorsement of water fluoridation by these prominent and recognized experts, we are confident that water fluoridation is the right public health provision for our community. We are taking this opportunity to reaffirm our support, as the Board of Health, for continued fluoridation of water.

Please feel free to reach out to us for any reason.

Respectfully submitted,

Respectfully,

Ingestion of infant formula constituted from fluoridated water associated with IQ deficit

Till C, Green R, Flora D, Hornung R, Martinez-Mier EA, Blazer M, et al. Fluoride exposure from infant formula and child IQ in a Canadian birth cohort. *Environ Int* 2020;134:105315.

Question Among otherwise normal preschool children, what is the association between fluoridated water used to constitute formula as infants/toddlers and IQ?

Design Multicenter, prospective study drawn from participants in the Maternal-Infant Research on Environmental Chemicals (MIREC) program.

Setting 6 cities across Canada.

Participants 398 mother-child dyads, the children of which were 3-4 years old.

Intervention Wechsler Primary and Preschool Scale of Intelligence-III.

Outcomes IQ score.

Main Results 38% of the dyads lived in cities with fluoridated water. An increase of 0.5 mg/L in water fluoride concentration corresponded to a 9.3- and 6.2-point decrement in Performance IQ among both formula-fed (95% CI: -13.77 to -4.76) and breast-fed children (95% CI: -10.45 to -1.94), respectively.

Conclusions Ingestion of formula constituted from fluoridated water is associated with Performance IQ deficits.

Commentary This study by Till et al used data from the MIREC Study to demonstrate that fluoride intake from infant formula constituted from tap water is associated with lower performance IQ at age 3-4 years. Despite some limitations, eg, the use of estimated vs directly measured exposures to fluoride, the possibility of bias or confounding appears low. The results are consistent with increasing evidence suggesting that early life exposure to fluoride (prenatal and infancy) is associated with adverse neurobehavioral impacts. Evidence includes experimental studies in rodents as well as 3 recent longitudinal birth cohort studies (1 involving MIREC and 2 involving ourselves and colleagues) demonstrating significant associations between individual measures of prenatal fluoride exposure and lower performance on offspring measures of intelligence and behavior.¹⁻³ Overall, these studies inform the ongoing debate over the benefits vs risks associated with the fluoridation of water. Clearly, more research is needed. Meanwhile, since the beneficial effects of fluoride predominantly occur at the tooth surface after teeth have erupted, whereas fluoride is not essential for growth and development, a cautious step could be avoidance of fluoridated products and water by women during pregnancy and by infants during the first 6 months of life.

Mandatory vaccine policies associated with increased vaccination rates and decreased measles incidence

Vaz OM, Ellingson MK, Weiss P, Jenness SM, Bardají A, Bednarczyk RA, et al. Mandatory Vaccination in Europe. *Pediatrics* 2020;145: pii e20190620.

Question Among children living in Europe, what is the association between mandatory vaccination and vaccine-preventable disease reduction?

Design Data analysis from the data banks of the European Centre for Disease Prevention and Control and the World Health Organization.

Setting 29 European countries.

Participants Children vaccinated.

Intervention Vaccination rates from 2006 to 2015 for measles, 2006 to 2016 for pertussis, and mandatory vaccination policies.

Outcomes Measles and pertussis vaccine coverage and the annual incidence of these diseases.

Main Results Mandatory vaccine policies were associated with higher vaccination prevalence, 3.71% (95% CI, 1.68 - 5.74) and 2.14% (95% CI, 0.13 to 4.15) for measles and pertussis, respectively. Some countries imposed a monetary penalty for non-compliance. Every €500 increase in the maximum penalty demonstrated an increase of 0.8% and 1.1% for measles pertussis vaccination prevalence, respectively ($P < .0001$ for both). Only countries without non-medical exemptions demonstrated an association with a lower measles rate compared with countries without a mandatory vaccine policy, adjusted incidence rate ratio, 0.14 (95% CI, 0.05 to 0.36). Pertussis rates were not statistically different.

Conclusions Mandatory vaccination policies were associated with higher vaccination rates and a decreased measles incidence.

A new perspective on metals and other contaminants in fluoridation chemicals*

Phyllis J. Mullenix

Andover, MA, USA

Background: Fluoride additives contain metal contaminants that must be diluted to meet drinking water regulations. However, each raw additive batch supplied to water facilities does not come labeled with concentrations per contaminant. This omission distorts exposure profiles and the risks associated with accidents and routine use.

Objectives: This study provides an independent determination of the metal content of raw fluoride products.

Methods: Metal concentrations were analyzed in three hydrofluorosilicic acid (HFS) and four sodium fluoride (NaF) samples using inductively coupled plasma-atomic emission spectrometry. Arsenic levels were confirmed using graphite furnace atomic absorption analysis.

Results: Results show that metal content varies with batch, and all HFS samples contained arsenic (4.9–56.0 ppm) or arsenic in addition to lead (10.3 ppm). Two NaF samples contained barium (13.3–18.0 ppm) instead. All HFS (212–415 ppm) and NaF (3312–3630 ppm) additives contained a surprising amount of aluminum.

Conclusions: Such contaminant content creates a regulatory blind spot that jeopardizes any safe use of fluoride additives.

Keywords: Fluoride additives, Metal contaminants, Drinking water regulations

Background

Prior studies have linked human ingestion of heavy metals to agricultural applications of municipal wastes and commercial fertilizers.^{1–3} However, fluoride additives used in the water fluoridation process are another potential source for metal ingestion by humans and have not yet been adequately investigated. The production of fluoride additive involves phosphate rock, which contains cadmium (Cd), arsenic (As), lead (Pb), chromium (Cr), mercury (Hg), nickel (Ni), vanadium (V), uranium (U), and other radionuclides and metals at levels that vary by geographical origin.^{2–4} Metal contaminants in fluoride additives are a potential contamination source of the water supply.

In an attempt to limit hazardous exposures via drinking water, the US Environmental Protection Agency (EPA) requires that quality and safety assurance programs screen the metal content of drinking water after the use of additives like fluorosilicic acid (H_2SiF_6 or hydrofluorosilicic acid [HFS]), sodium fluorosilicate (Na_2SiF_6), and sodium

fluoride (NaF). The EPA recommends that finished drinking water have fluoride at the desired levels of ≤ 1.2 mg/l (less than one-third the EPA Maximum Contaminant Level, MCL), while other contaminants stay at or below levels considered safe ($<$ one-tenth the respective EPA MCL).^{5,6} Silicate has no MCL, but there is a 16 mg/l maximum drinking water level (MDWL) restriction, and radionuclide levels are not to exceed detection limits of EPA Test Method 900.0.^{5–7}

Both the American Water Works Association (AWWA) and the National Sanitation Foundation International (NSF) provide guidelines for the selection and use of fluoride additives. Quality controls consist of multiple standards (i.e., ANSI/NSF Standards 60 and 61, ANSI/AWWA B701–B703) and testing and certification programs.^{5,6,8} When an NSF certified additive is dosed into water according to the specified maximum use level (MUL) (typically 6.0 mg/l for HFS; 2.3 mg/l for NaF; 2.0 mg/l for Na_2SiF_6), the dilution process should limit the doses of metals delivered to the public via fluoridation. However, data from 2000 to 2006 and 2007 to 2011 show that controlled dilution procedures resulted in detectable levels of up to 13 metal contaminants and that in finished drinking water samples 43–50% had detectable As; <1 –2% had Pb; 0–1% had Cd; and

*Presented in part at the North Jersey District Water Supply Commission's Educational Seminar "Pharmaceutical Contaminants in the Water Treatment Industry," Wanaque, New Jersey, July 14, 2009.

<1% had Cr.^{5,6} Controlled dilution is intended to restrict contaminants to concentrations at or below the ANSI/NSF Standard 60 single product allowable concentration (SPAC) limits (0.1 MCL for contaminants except fluoride) and thereby lessen concern for metal exposure originating from fluoridation.

The controlled dilution process does not protect public safety in the case of accidents and therefore it is necessary to shift focus from regulation of diluted fluoride products to raw fluoride additives – which are never contaminant free. In the United States, state and local agencies are responsible for regulating the use of raw fluoride additives and on numerous occasions these authorities have had to deal with mishandling accidents.^{9–22} Such accidents fall into one of three categories: water distribution overfeeds (fluoride levels ≥ 4 or ≥ 7 mg/l in school systems); non-overfeeds (fluoride levels >1.2 mg/l but <4 or <7 mg/l in school systems); and industrial accidents during the handling, transport, or storage of additives at or near water treatment facilities. Regardless of category, fluoride is typically the only contaminant identified or monitored during accidents. Overfeed accidents occur when the MUL is exceeded and excess fluoride additive enters the drinking water. This can result in illnesses in children and adults, attributed to fluoride and not to fluoride combined with other contaminants such as As and Pb.^{23–26} In non-overfeed accidents, the public may not be informed for up to 12 months that their drinking water has fluoride levels >1.2 mg/l as long as the MCL of 4 mg/l is not exceeded. Furthermore, the public is never informed about the concentration levels of the other contaminants also present in the water.

In an industrial accident in Utah where a water facility storage tank ruptured and released 300 gallons of HFS, authorities anticipated the high levels of fluoride (495 ppm) in the nearby waterway, but did not anticipate the coexisting 42.6 ppb arsenic discovered during the follow-up investigation. The manufacturer's material safety data sheet (MSDS) on file for the spilled HFS did not warn of any potential arsenic content.²⁷ This example demonstrates how gaps in regulation allow unreported metal content to become potential health risks during accidental exposure to raw or improperly diluted fluoride additives.

Contaminant content defines exposure and determines health impact. It is well established that batch-to-batch variation in contaminant content can change biological response and that even trace amounts of contaminants can lower the threshold dose for an effect, particularly when there are synergistic interactions and the overall effect is greater than the sum of effects caused by contaminants acting alone.²⁸

Synergism between contaminants fosters an underestimation of risks, like that occurring with combinations of Pb, As, Cd, and Cr or fluoride coexisting with aluminum or beryllium.^{29–35} Combinations of contaminants can also trigger chemical degradation, generating decomposition products with toxicity greater than that of the original compounds. In a previous trace contaminant study of commercially available HFS samples, one in four samples had signs of decomposition where an unexpectedly high level of hydrofluoric acid (3.3%) exceeded the AWWA standard (1%).³⁶

The MSDS's for fluoride additives do not specify threshold limit values for decomposition products such as hydrogen fluoride. While they do warn against combining fluoride with metals to avoid corrosion, they do not describe the risks that decomposition creates for workers as a result of airborne contamination. Although the MSDS's for HFS and NaF additives list a threshold limit value (TLV) of 2.5 mg(F)/m³, they avoid the 0.5 ppm TLV (0.41 mg(F)/m³ at 25°C and 760 Torr) for occupational exposure to hydrogen fluoride.³⁷ This incomplete disclosure can result in unexpected outcomes, like that encountered by manufacturers of fluoroether compounds (i.e. sevoflurane) when trace amounts of metal oxides from metallic or glass surfaces of containers or medical devices initiated chemical degradation to form highly toxic levels of hydrogen fluoride, hydrofluoric acid, and silicon tetrafluoride.^{38–41} Any metal initiated degradation of fluorinated compounds is important to consider, especially since drinking water increasingly contains fluorinated pharmaceuticals.^{42,43} Beryllium oxyfluoride, barium fluoride, or magnesium fluoride are acutely more toxic than compounds such as sodium fluoride, calcium fluoride, or magnesium oxide.^{44–46} Given established hierarchies in potential toxicity, it is important to consider the risks associated with the combination of metals and fluoride in an exposure scenario.

To understand the risks associated with using fluoride additives, it is necessary to first evaluate the metal content of the raw fluoride product before the application of controlled dilution procedures. While NSF programs require annual unannounced inspections of fluoride additive suppliers, inspection results are kept private by nondisclosure agreements to protect business interests. There is no routine screening for discrepancies between inspection results and the manufacturer's Certificate of Analysis or MSDS sent with each additive batch.^{5,6} Description of the metal content of raw additives is typically limited to total percent levels (i.e., heavy metals such as lead, $<0.0200\%$) and not the actual concentration of metal per batch. Furthermore, many of the additives imported to the US have errors in their Certificates

of Analyses.²⁷ Regardless, there are currently no routine measures of metal content per additive batch before use. Currently, fluoride additive purchases are based on AWWA and NSF Standard 60 certification, availability, and cost, but not on metal contaminant content. As of 2013, only one New Hampshire water facility had a low arsenic requirement for fluoride additives (personal communication, D. Paris, Manchester Water Treatment Plant). Utah recently passed legislation (HB 72) requiring the full disclosure of metal contaminant levels in raw fluoride additives.⁴⁷

The aim of this study was to analyze the metal content of NSF certified raw fluoride additives. Unlike previous studies of additive chemical composition, the analyses presented in this study are independent of chemical supplier data, address both liquid (HFS) and solid (NaF) forms of fluoride additives, and focus on multiple metals, not just arsenic.^{36,48} This paper also expands on safety considerations in the event of an accident, arguing that NSF's dilution approach, which focuses on one contaminant at a time, is inadequate. Such data are crucial as water facilities that fluoridate are adding potentially harmful contaminants, some carcinogenic, to drinking water.

Methods

Fluoride additives

All the fluoride additives analyzed in this study were commercially available products intended for fluoridation use at US water facilities.

Three HFS additives (HFS-1, HFS-2, and HFS-3) from different batch shipments were selected for study. Each sample was a clear liquid and consisted of 23–25% acid. The HFS additives originated from the US or Mexico (Juarez) and were labeled as AWWA/NSF certified. The origin of individual samples could not be established because manufacturer shipments were stored in common bulk tanks not cleaned between batches. The HFS samples selected for laboratory study were shipped and stored in polyethylene containers prior to analysis.

Four samples of solid fluoride additives were obtained for laboratory testing. One NaF sample (NaF-1) was in white powder form, while the remaining samples (NaF-2, NaF-3, and NaF-4) were in granular form. Each sample was taken from a different batch shipment and all samples selected for laboratory analysis were shipped and stored in individual Teflon containers. All NaF samples originated from Shanghai, China and met AWWA and NSF Standard requirements. Cross-contamination between domestic and foreign made dry additives was unlikely because US production ceased years ago. In contrast, cross-contamination between shipments of different fluoride compounds, some

intended for purposes other than fluoridation, could not be ruled out. Cross-contamination between fluoride salts originating from different countries could also not be ruled out. US suppliers repackage foreign made fluoride salts using the same equipment regardless of source and there is no wet cleaning between uses.

Analytical procedures

All fluoride additive samples required dilution in order to be within the analytical range of the testing instruments. Concentration levels of aluminum, antimony, arsenic, barium, beryllium, cadmium, calcium, chromium, copper, iron, lead, magnesium, manganese, molybdenum, nickel, potassium, selenium, silver, thallium, vanadium, and zinc were determined using EPA's Method 200.7 for inductively coupled plasma-atomic emission spectrometry (ICP).⁷ Percentage levels of fluoride and sodium were determined for all additive samples and the percentage of silicon dioxide was determined in the NaF samples and in the samples of HFS-1 and -2. The ICP determined arsenic results were confirmed by reassessment of levels using Graphite Furnace Atomic Absorption (GFAA) analysis.

Report values

Concentration values (micrograms per milliliter for liquid additives and micrograms per gram for solid additives) were expressed as parts per million (ppm) and reported when they equaled or exceeded the method detection limit (MDL) established per analyte. All concentration levels presented in the results, including those for MDL determinations, were from the raw (undiluted) fluoride additive. Each concentration value reported was an average of duplicate measures for intra-laboratory verification.

Results

Some of the results from the chemical analysis were consistent with the content expected of an AWWA and NSF certified fluoride additive. The 23–25% HFS samples contained 18–19% fluoride and sodium content of the four NaF samples met expectations (56%, NaF-1; 56.8%, NaF-2; 54.9%, NaF-3; and 57.4%, NaF-4). The sodium content of the HFS additives was 0.11% (HFS-1), 0.14% (HFS-2), and 0.05% (HFS-3). Based on two measurements, the SiO₂ content of the HFS samples ranged from 16.15% (HFS-2) to 16.55% (HFS-1). The SiO₂ content of the NaF samples was higher than expected: 24.6% in NaF-1, 26.6% in NaF-2, 26.0% in NaF-3, and 25.7% in NaF-4.

Of the 21 metal contaminants analyzed, 12 had concentration levels that were below established MDL's in the raw HFS and NaF additive samples. The contaminants with insignificant concentrations

Table 1 Contaminants with concentration levels below MDL's in raw 23–25% hydrofluorosilicic acid (HFS-1, -2, and -3) and sodium fluoride (NaF-1, -2, -3, and -4) additive samples

Analyte	MDL* (ppm)
Antimony	10.0
Beryllium	1.5

and the established MDL's per contaminant are provided in Table 1.

The remaining contaminants, including aluminum, arsenic, barium, calcium, iron, lead, magnesium, potassium, and zinc, had concentration levels that exceeded MDL's in at least one of the fluoride additive samples tested. The contaminant concentrations for the liquid HFS samples are presented in Table 2. Contaminant concentrations for the dry salt NaF additives are listed in Table 3.

Arsenic, lead, and zinc were found only in HFS additives. Arsenic in particular was present most consistently. The GFAA analysis confirmed reportable levels of arsenic in the three HFS additive samples (4.9, 34.0, and 56.0 ppm, Table 2). The HFS sample with the lowest arsenic level also contained a reportable level of lead (10.28 ppm, HFS-3, Table 2).

Barium was the only metal contaminant found exclusively in NaF additive samples (13.3 ppm, NaF-1 and 18.0 ppm, NaF-3; Table 3). Reportable levels of aluminum, calcium, iron, magnesium, and potassium were found in both the liquid and dry salt fluoride additives and concentration levels were similar in HFS and NaF samples. Concentration levels of potassium and aluminum were higher in the dry salt additives; with aluminum concentrations in the NaF samples nearly 10-fold higher than those in HFS samples. In general, aluminum was the contaminant with the highest concentration levels.

Discussion

This study demonstrates that the metal contaminant content of raw fluoride additives is highly batch-dependent. There was as much as a 10-fold difference between batches in the concentration levels of arsenic, lead, and barium, contaminants classified as a risk to human health by the National Primary

Table 2 Metal contaminant concentrations found using ICP analysis of raw 23–25% hydrofluosilicic acid additives (HFS-1, -2, and -3). Values are not corrected for density of 1.2 g/ml

Drinking Water Regulations.^{49,50} As no two additive samples were found to have the same exposure profile in this study, assumptions about metal content are unreliable if based on manufacturer source or certification by NSF. Although the AWWA affirms the HFS purchasers' right to know the source of a raw product when manufactured outside North America,⁸ such information is meaningless when there is cross-contamination between HFS shipments stored in common tanks. Likewise, cross-contamination may impact metal content when all imported salt additives, regardless of source, chemical form, or intended usage are handled in the same repackaging equipment. The fact that NaF samples in this study were obtained from bulk supplies not yet repackaged, suggests that the unexpectedly high SiO₂ levels were more a function of mislabeling than cross-contamination. Contrary to label and lot number information, this analysis revealed that salt samples were likely an unidentified mix of NaF and Na₂SiF₆, two frequently used fluoride additives with different MUL's and chemical properties. Whether mislabeling or cross-contamination, the findings here indicate that users of fluoride additives can expect unpredictable amounts of metal contamination.

The only consistencies observed among the additives was that certain contaminants were always

absent (e.g., antimony, silver, and vanadium), while others were always present (e.g., aluminum, magnesium, and iron). The absent contaminants are consistent with those absent in EPA test samples of tap, pond, and well water.⁷ When compared to the content reported for other substances (Table 4), contaminant concentration levels of raw HFS additives were typically much higher than those found in tap water or in industrial or sewage treatment primary effluents.^{5-7,51} Moreover, contaminant concentration levels in raw NaF additives were much lower than those reported for contaminated solids with two notable exceptions. Barium and aluminum levels approached those that the EPA found in samples of electroplating sludge, river sediment, and hazardous soils (Table 4). The high and unpredictable contaminant levels found in the samples indicate the upper limits of possible exposures during fluoridation accidents when dilution's mitigating influence is inaccurate or altogether absent. Thus, the results here indicate that NSF's dilution approach is inappropriate. Employees who handle fluoride additives require a fail-safe strategy that takes into account the variable and hazardous metal content of the additives, both for their safety and the safety of consumers.

Arsenic has been reported as the "limiting constituent" for HFS dosage when controlling contaminants

Table 4 Measured contaminant levels in raw fluoride additives compared with measurements in environmental test samples

Analyte	Concentration levels (ppm) in raw fluoride additives*	Concentration levels (ppm) in aqueous and solid matrices reported in the literature
Arsenic		
HFS	4.9–56.0	0.0006 or 0.00166 average in tap water fluoridated by NSF certified HFS [†] ; <0.02 in industrial effluent [‡]

in finished drinking water.³⁶ The range of arsenic levels found in raw HFS samples was 4.9–56 ppm, similar to previous research analyzing raw HFS additives (9.4–58.5⁵² and 28–60 ppm⁴⁸). Dilution reduces the parts per million arsenic levels of raw HFS additives, to parts per billion ($\mu\text{g/l}$) arsenic levels in finished drinking water, allowing concentrations to meet established enforceable drinking water regulations. The current NSF/ANSI standard for arsenic is 0.001 ppm (1 ppb based on an MCL of 0.010 ppm).^{5,6,49,50} Table 5 provides the arsenic levels expected in finished drinking water when HFS is used for fluoridation. For example, Weng *et al.* calculated that 60 ppm arsenic in raw HFS additives would contribute 0.245 $\mu\text{g/l}$ arsenic in finished drinking water fluoridated at 1 ppm (Table 5).⁴⁸ Using this calculation, the 56.0 ppm arsenic found here in one HFS sample would become 0.224 $\mu\text{g/l}$ arsenic in finished drinking water when fluoridated at 1 ppm. As long as dilution is controlled and fluoridation stays at 1 ppm, arsenic levels (0.019–0.245 ppb in Table 5) in finished drinking water stay below the 1 ppb Standard 60 level. However, during fluoride overfeeds only the HFS additives with the lowest arsenic levels (4.9 $\mu\text{g/l}$ in Table 5) can produce drinking water where arsenic meets the Standard 60 level of 1 ppb. Moreover, fluoride non-overfeeds risk exceeding the Standard 60 level of 1 ppb arsenic when HFS additives contain high levels of arsenic (56.0–60 $\mu\text{g/l}$). The risk is even greater when there are multiple sources (e.g., natural erosion or non-fluoride water treatment chemicals) contributing arsenic to finished drinking water. Water treatment chemicals other than fluoride additives can contribute up to 0.061 μg arsenic/l of finished drinking water.⁴⁸ Combine this 0.061 $\mu\text{g/l}$ arsenic with the 0.956 or 0.873 $\mu\text{g/l}$ arsenic contributed by fluoride additives (raw additives containing 56 or 60 ppm arsenic; Table 5), and the total either exceeds the 1 ppb standard or comes close enough that there is no allowance for input from natural sources. Fluoride, but

not arsenic, is typically monitored daily when treated water enters the water delivery system. In contrast, arsenic levels are only checked quarterly or annually, depending on individual facility protocols. While HFS related non-overfeeds mean that fluoride levels are below the 4 ppm MCL/MCLG standard, it does not necessarily mean that arsenic is below the 1 ppb standard, or that arsenic is even the highest concentration contaminant of concern. The low arsenic HFS additive identified in this study (4.9 ppm arsenic) also contained 10.3 ppm lead (current NSF/ANSI standard=0.0015 ppm; MCL=0.015 ppm). The NaF additives contained neither arsenic nor lead, but did contain up to 18.0 ppm barium (current NSF/ANSI standard=0.2 ppm; MCL=2 ppm).^{5,6,49,50} Therefore, the use of arsenic as the “limiting constituent” may not be appropriate.

The arsenic, lead, and barium content of raw fluoride additives pit health risks against technological feasibility and drinking water regulations. For these contaminants, standards are based on health concerns, technology, and cost.^{49,50} Technological allowances are for geogenic sources that contribute substantially to source water contamination. In short, standards are relaxed to allow for arsenic, lead, and barium to be introduced into drinking water via erosion of natural deposits.^{49,50} When present in fluoride additives, these contaminants are added to natural sources of contaminants, complicating control over site-specific erosion problems and in turn the estimation of total contaminant exposure. Without such allowances, the standards would be solely health-based and provide margins of safety adequate to protect against adverse health effects. Such health-based standards are the EPA’s Maximum Contaminant Level Goals (MCLG’s), which are set at 0 ppm for arsenic and lead, and 2 ppm for barium.^{49,50} The 0 ppm MCLG for arsenic was established because arsenic exposure is associated with skin and cardiovascular damage, lung cancer,

Table 5 Raw HFS additive arsenic content converted to concentration levels expected in finished drinking water with fluoridation at desired (1 ppm), non-overfeed (3.9 ppm), and overfeed (24–200 ppm) dilutions

Raw HFS additives – analytical results for arsenic (ppm)	Finished drinking water – calculated estimate* of arsenic concentrations ($\mu\text{g/l}$) during desired, non-overfeed, and overfeed fluoride situations		
	Desired F-level 1.0 ppm	Non-overfeed F-level 3.9 ppm [‡]	Overfeed F-level 24 ppm [§]
56.0 [†]	0.224	0.873	5.38
34.0 [†]	0.136	0.530	3.26
4.9 [†]	0.019	0.076	0.470
60	0.245 [†]	0.956	5.88
28	0.114 [†]	0.446	2.75

and bladder cancer. Similarly, the 0 ppm MCLG was established for lead because lead exposure can cause physical and mental developmental delays, attention and learning deficit disorders, kidney damage and hypertension. The 2 ppm MCLG for barium was created because of its hypertensive effects. The MCLG of zero indicates that any amount of lead or arsenic in drinking water, whether derived from natural or artificial sources, poses a risk to human health.

While it is known that arsenic in HFS increases the numbers of lung and bladder cancers in the United States,⁵³ no consideration has been given to the arsenic and lead levels in HFS overfeeds and non-overfeeds. Non-overfeeds are a particularly insidious exposure since they are unreported for months and total contaminant contribution is ignored. As water operators continue to focus only on desired fluoride levels (1 ppm), health consequences will be systematically underestimated and potential carcinogens may enter into the public water system.

The high levels of aluminum in raw fluoride additives raise questions about the adequacy of current drinking water regulations. Along with calcium, iron, and magnesium, aluminum is regulated under the National Secondary Drinking Water Regulations as a technical and a esthetic nuisance, not as a risk to human health.^{49,50} Some nuisance contaminants are considered essential and possibly protective against cardiovascular and cerebrovascular mortality.^{54,55} In drinking water, aluminum and iron can cause undesirable color, tastes, and/or odors, but neither has an enforceable MCL for health-based concerns. Federal regulations do not require state health agencies and public water systems to monitor aluminum levels in water supplies, and aluminum levels are not determined when an NSF certified fluoride additive is dosed into water at a MUL.^{5,6,49,50} Aluminum is not a limiting constituent for any water treatment chemical and is only restricted when an aluminum-based flocculant is used to remove naturally occurring excess fluoride and/or unwanted color and turbidity from water supplies.^{36,56,57} After this removal process, residual aluminum levels should not exceed 0.2 ppm. This concentrations is low enough that drinking water contributes a much smaller proportion of the lifetime burden of aluminum than food.^{49,50,58,59} However, this flocculation limit does not relate to the later process of fluoridation, which is the last step in water treatment before drinking water is delivered. It is assumed that NaF additives contain only small amounts of aluminum.⁶⁰ This is not a safe assumption given the 212–415 ppm aluminum found in the HFS samples and the near electroplating sludge levels (3312–3630 ppm) found in the NaF samples (Table 4). Findings from this study indicate that

fluoride additives deliver a larger proportion of the daily aluminum intake than previously realized, and unknown concentrations of aluminum fluoride complexes are reaching consumers via fluoridation.

Concerns that aluminum in drinking water threatens health are countered by claims of low toxic potential due to poor gastrointestinal (GI) absorption.⁶¹ The level of aluminohydroxide complexes in city water supplies ($21.8 \pm 10 \mu\text{g/l}^{58}$) seems trivial compared to the 400 mg of aluminum hydroxide found in one over the counter antacid tablet. However, this comparison is misleading. Although only a small portion of the antacid aluminum gets absorbed, it is enough to accumulate and cause premature osteoporosis, encephalopathy, and proximal myopathy during renal insufficiency.⁶² Manufacturers of antacids counterbalance aluminum with magnesium hydroxide in order to cancel the adverse effects the two metals have on the bowel.⁶² Furthermore, patients are warned not to take antacids concomitantly with certain medications because aluminum hinders essential drug absorption by forming Al-drug insoluble complexes.⁶² This exceptional binding strength is why aluminum is no longer used as a phosphate binder to treat renal osteodystrophy. It promotes adynamic bone disease (low bone turnover), anemia, myopathy, and dementia.⁶³ In short, aluminum exposure via antacids is not comparable to exposure from drinking water. Antacids contain aluminum in the hydroxide form. Aluminum in food additives is usually in the form of a sulfate, silicate, or phosphate,⁶⁴ and human absorption of aluminum sulfates and silicates is largely unknown, while that of relatively insoluble aluminum phosphates depends upon the amounts consumed.⁶⁵ Gastrointestinal absorption of aluminum varies by quantity and chemical form.^{66,67} Drinking water contains multiple forms of aluminum, including aluminum-fluoride complexes, which are readily absorbed in the GI tract and cross the blood-brain barrier.^{32,68,69} It is the aluminum-fluoride complex form that has the greatest potential for biological impact, where toxicity stems from mimicking gamma-phosphate, altering enzyme activity and activating guanine nucleotide-binding proteins (G-proteins), which are integral to endocrine and nervous system functions.^{60,70–78} Al-fluoride complexes have been shown to be markedly more toxic than fluoride alone regarding deposition of aluminum in the brain and kidney and cerebrovascular and neuronal integrity.³² The much greater biological impact of the Al-fluoride complex, or fluoride coexisting with aluminum or beryllium, constitutes a threat to human health no longer dismissible on the basis of poor GI absorption.

Contaminant interactions should be considered in determining drinking water regulations. The finding of high aluminum levels in raw fluoride samples

underscores the inadequacy of regulations based on SPAC limits. There is no justification for the disparate limits, 0.2 ppm for aluminum and 1.2 ppm for fluoride, especially when the greatest toxic concern is the Al-fluoride complex. To build in a margin of safety, other contaminants have limits that are one-tenth their MCL. In contrast, the 1.2 ppm fluoride limit is less than one-third its MCL, providing no margin of safety to cover the potential toxicity of Al-fluoride complexes. While prior studies have investigated the potential link between Alzheimer's disease and aluminum in drinking water at levels as low as 0.1–0.2 ppm,^{79–82} it may be more important to investigate the association between Alzheimer's and levels of Al-fluoride complexes.

While many variables influence Al-fluoride complex formation, control over the formation starts with the disclosure of aluminum content in raw fluoride additives. When aluminum is only regulated as a water quality nuisance, only fluoride is considered for its potential health effects. Too narrow a focus on fluoride artificially limits populations at risk to those with compromised fluoride excretion (renal insufficiency), excluding those with higher than normal aluminum absorption (e.g., the elderly, Alzheimer and Down's syndrome patients^{83,84}). This shortsighted exclusion is avoidable if drinking water regulations addressed exposures to Al-fluoride complexes in addition to individual aluminum or fluoride levels.

In summary, raw fluoride additives contain significant levels of arsenic, lead, barium, and aluminum not addressed by current regulations with health-based standards. These raw product levels establish the upper limits of exposure in the event of fluoride overfeeds, non-overfeeds, and industrial accidents. Although the findings of this study are limited by small numbers of samples and manufacturing sources, they highlight flaws in the quality control of NSF certification. Controlled dilution procedures needed to meet NSF/ANSI standards camouflage the fact that metal contaminants are being removed from water sources only to be returned to finished water supplies via fluoridation. The use of fluoride additives assures that some risk is passed to the consumer, especially with regard to arsenic, lead, and non-overfeed levels of fluoride (1.2–4 ppm) that can persist undisclosed up to a year. Since January 2011, there has been a proposed recommendation to lower the optimum fluoridation level to 0.7 ppm. This proposal remains without regulatory standing and has been ignored. Considering this study's findings, the following recommendations outline controls needed to fill the gaps in current regulations:

1. All metal contaminants with concentrations that reach or exceed MDL's of analytical instrumentation should be identified per batch shipment,

regardless of source, before being used as a treatment chemical in public water supplies. Records of actual contaminant concentrations should be kept and made available to the public on request and to first responders during accidental spills.

2. Fluoridation levels should not exceed 0.4 ppm (one-tenth the fluoride MCL) in order to provide a margin of safety for interacting contaminants. Fluoridation above 0.4 ppm should not be attempted unless the aluminum and beryllium in raw additives are at levels below MDL's.
3. Raw additives with low arsenic, lead, and barium levels should be used when source waters contain these contaminants in naturally high concentrations. If such additives are unobtainable, the use of fluoride additives should be discontinued.
4. In conjunction with the use of fluoride additives, aluminum should have an established MCL and be regulated under the National Primary Drinking Water Regulations.

There must be a concerted effort to improve transparency with respect to the contaminant content of raw fluoride additives. Adopting the above recommendations would be a major step in alleviating the growing concerns for safety.

Is Water Fluoridation Effective?

According to most major sources, estimates of fluoridation effectiveness amount to at most a reduction of only one-half cavity per child. Low end estimates find **no significant reduction at all**. Children aged 6-17 average 2.1 cavities in their permanent teeth¹:

- Cochrane Collaboration² (2015): 26% (**0.5 cavity per child**)
- CDC³ (2018): 25% (**0.5 cavity per child**)
- Iowa Fluoride Study⁴ (2018): **No significant reduction**
- World Health Organization data⁵ (2005): **No evidence of fluoridation's effectiveness**

There is already a consensus including CDC, Cochrane Collaboration, the Iowa Fluoride Study and others that fluoride's effectiveness in preventing cavities is mainly topical (not swallowed).

The **Cochrane Collaboration** is considered the gold standard of evaluating effectiveness. It said the cavity reduction referenced above was **"based predominantly on old studies and may not be applicable today."**

"Over 97% of the 155 studies were at a high risk of bias, which reduces the overall quality of the results... We did not identify any evidence... to determine the effectiveness of water fluoridation for preventing caries in adults... There is insufficient evidence to determine whether water fluoridation results in a change in disparities in caries levels across socio-economic status."

The **Iowa Fluoride Study (IFS)**, funded by the National Institutes of Health, is the most comprehensive, ongoing research project in the U.S., the only one measuring all sources of fluoride ingestion. The 2018 study from IFS referenced above found no significant correlation between ingested fluoride and cavity reduction, further validating a 2009 study⁶ from IFS that stated:

*"... achieving a caries-free status may have relatively little to do with fluoride **intake** (emphasis in the original) ... recommending an 'optimal' fluoride intake is problematic."*

Finally, World Health Organization data show cavity rates in children (age 12) have dropped as much in nations that don't fluoridate (darker solid lines) as in nations that do (red/yellow dotted lines). (See graph)

**Tooth Decay Trends:
Fluoridated vs. Unfluoridated Countries**

(12 year olds; all data from World Health Organization; salt F countries excluded)

November 22, 2016

Gina McCarthy, Administrator
Environmental Protection Agency
Ariel Rios Building
1200 Pennsylvania Avenue, NW
Washington, D.C. 20460

Dear Administrator McCarthy:

Pursuant to section 21 of the Toxic Substances Control Act ("TSCA"), 15 U.S.C. § 2620, the Fluoride Action Network, Food & Water Watch, Organic Consumers Association, American Academy of Environmental Medicine, International Academy of Oral Medicine and Toxicology, Moms Against Fluoridation, and undersigned individuals (collectively, "Petitioners") hereby petition the U.S. Environmental Protection Agency to protect the public and susceptible subpopulations from the neurotoxic risks of fluoride by banning the addition of fluoridation chemicals to water.

Under Section 6 of TSCA, EPA is invested with the authority to prohibit the "particular use" of a chemical substance if the use presents an unreasonable risk to the general public or susceptible subpopulations. 15 U.S.C. § 2605(a). EPA has recognized that its authority to regulate chemical substances under TSCA includes the authority to prohibit *drinking water additives*.

EPA should exercise its authority under TSCA to prohibit fluoridation additives because application of the Agency's own *Guidelines for Neurotoxicity Risk Assessment* to the existing database on fluoride shows that (1) neurotoxicity is a hazard of fluoride exposure, and (2) the reference dose that would reasonably protect against this hazard is incompatible with the doses now ingested by millions of Americans in fluoridated areas. In fact, the amount of fluoride now regularly consumed by many people in fluoridated areas *exceeds* the doses *repeatedly* linked to IQ loss and other neurotoxic effects; with certain subpopulations standing at elevated risk of harm, including infants, young children, elderly populations, and those with dietary deficiencies, renal impairment, and/or genetic predispositions.

The risk to the brain posed by fluoridation additives is an unreasonable risk because, *inter alia*, it is now understood that fluoride's predominant effect on tooth decay comes from *topical* contact with teeth, not *ingestion*. Since there is little benefit in *swallowing* fluoride, there is little justification in exposing the public to *any* risk of fluoride neurotoxicity, particularly via a source as essential to human sustenance as the public drinking water and the many processed foods and beverages made therefrom. The addition of fluoridation chemicals to water thus represents the very type of unreasonable risk that EPA is duly authorized to prohibit pursuant to its powers and responsibilities under Section 6 of TSCA, and Petitioners urge the Agency to exercise its authority to do so.

THE PETITIONERS

ORGANIZATIONS:

American Academy of Environmental Medicine (AAEM) was founded in 1965, and is an international association of physicians and other professionals that provides research and education in the recognition, treatment and prevention of illnesses induced by exposures to biological and chemical agents encountered in air, food and water.

Fluoride Action Network (FAN), was founded in 2000 as a project of the American Environmental Health Studies Project, Inc. FAN is an organization of scientists, doctors, dentists, environmental health researchers, and concerned citizens working to raise awareness about the impact of current fluoride exposures on human health.

Food & Water Watch (FWW) is a national non-profit public interest consumer organization, based in Washington, D.C. that works to ensure safe food and clean water. FWW has worked on many emerging technologies that impact our food supply, by educating consumers, the media, and policymakers about the impact on the food system and public health and by calling for appropriate regulation.

The **International Academy of Oral Medicine & Toxicology (IAOMT)** has been dedicated to its mission of protecting public health through the practice of biological dentistry since it was founded in 1984. A worldwide organization of over 800 dentists, physicians, and research professionals in more than 14 countries, IAOMT's mission is accomplished by funding and promoting relevant research, accumulating and disseminating scientific information, investigating and promoting non-invasive scientifically valid therapies, and educating medical professionals, policy makers, and the general public.

Moms Against Fluoridation is a national nonprofit with a mission to increase awareness of the unsafe and unethical practice of artificial water fluoridation in America today.

Organic Consumers Association is a nationwide grassroots public interest organization dealing with issues of food safety, industrial agriculture, and genetic engineering while promoting organic and sustainable agriculture.

INDIVIDUALS:

Audrey Adams, a resident of Renton, Washington (individually and on behalf of her son Kyle Adams); **Jacqueline Denton**, a resident of Asheville, North Carolina (individually and on behalf of her children Tayo Denton and Rumi Denton); **Valerie Green**, a resident of Silver Spring, Maryland (individually and on behalf of her children Joseph Scribner, Paxton Scribner, Savannah Scribner, Talia Scribner, and Violet Scribner); **Kristin Lavelle**, a resident of Berkeley, California (individually and on behalf of her son Neal Lavelle); and **Brenda Staudenmaier** from Green Bay, Wisconsin (individually and on behalf of her children Ko Staudenmaier and Hayden Staudenmaier).

I. INTRODUCTION

The addition of industrial-grade fluoride chemicals at a concentration of 0.7 to 1.2 mg/L to public water supplies for the purpose of preventing tooth decay is a common practice in the United States, with approximately 200 million Americans now consuming artificially fluoridated water. This practice, known as “water fluoridation,” is hailed as an effective practice by public health institutions in the U.S., but has been rejected by most of continental Europe without any demonstrable adverse effect on childhood caries rates.¹

Water fluoridation began in the U.S. in the 1940s on the premise that fluoride’s primary benefit to teeth comes from *ingestion*. (Fejerskov 2004). The consensus among dental researchers today, however, is that fluoride’s predominant benefit is *topical* not systemic. (NRC 2006, at 13; CDC 2001, at 4; Featherstone 2000). It is also now recognized that fluoride is not an essential nutrient. (NRC 1993, at 30; NRC 1989, at 235). Fluoride does not need to be swallowed, therefore, to prevent any disease, including tooth decay. By contrast, fluoride’s risks to health come from ingestion, including the spectrum of neurotoxic effects discussed below. Accordingly, a reasonable use of fluoride for caries prevention would aim to maximize its topical contact with teeth, while minimizing its ingestion. Topical fluoride products like toothpaste are compatible with this goal; fluoridating water supplies is not.

II. THE TOXIC SUBSTANCES CONTROL ACT (TSCA)

Section 6 of the Toxic Substances Control Act (TSCA) invests EPA with the authority and duty to take certain actions if it determines that “the manufacture, processing, distribution in commerce, use, or disposal of a chemical substance . . . presents an unreasonable risk of injury to health.” 15 U.S.C. § 2605(a). In making this determination, TSCA commands that EPA consider not only risks to the general public, but to “susceptible subpopulation[s]” as well. 15 U.S.C. § 2605(b)(4)(A). Further, TSCA commands that EPA conduct the risk evaluation “without consideration of costs or other nonrisk factors.” *Id.*

If EPA determines that a chemical substance presents an unreasonable risk to the general public or susceptible subpopulation(s), the Agency “shall” take action “to the extent necessary to protect adequately against such risk using the least burdensome requirements.” 15 U.S.C. § 2605(a). The actions that EPA may take include: (1) a complete prohibition on the manufacture, processing, and distribution of the substance or (2) a prohibition on a “particular use” of the substance. 15 U.S.C. § 2605(a)(1)–(3).

EPA’s authority to prohibit and regulate the use of chemical substances under TSCA encompasses drinking water additives. EPA recognized this in its June 12, 1979 Memorandum of Understanding with the FDA, in which the Agency stated unequivocally that it has authority “to regulate direct and indirect *additives to drinking water* as chemical substances and mixtures under TSCA.”² (EPA/FDA 1979)

¹ Tooth decay rates declined precipitously throughout the western world during the second half of the twentieth century, in both the *minority* of western countries that fluoridate water (e.g., Australia, Canada, Ireland, New Zealand, and the U.S.), and the majority of western countries that do not. (Cheng et al. 2007; Pizzo et al. 2007; Neurath 2005; Bratthall et al. 1996; Diesendorf 1986).

² As EPA explained, “[a]lthough Section 3(2)(B) of TSCA excludes from the definition of ‘chemical substance’ food and additives as defined under FFDCA, the implicit repeal by the [Safe Drinking Water Act] of FDA’s authority over

EPA may not consider costs when determining whether a risk exists, but it must do so when determining the appropriate course of action to protect against the risk. Specifically, EPA must consider: (1) “the effects of the chemical substance,” (2) “the magnitude of the exposure of human beings,” (3) “the benefits of the chemical substance,” and (4) “the reasonably ascertainable economic consequences of the rule.” 15 U.S.C. § 2605(c)(2)(A). The EPA shall also consider “whether technically and economically feasible alternatives . . . will be reasonably available as a substitute when the proposed prohibition or other restriction takes effect.” 15 U.S.C. § 2605(c)(2)(C).

Finally, EPA is authorized to take action under TSCA, *even if it has authority under other laws to address the risk*, so long as “it is in the public interest” to do so. 15 U.S.C. § 2608(b)(1). In determining whether it is in the public interest to take action under TSCA, EPA “*shall consider . . . all relevant aspects of the risk and a comparison of the estimated costs and efficiencies of the action to be taken under [TSCA] and an action to be taken under such other law to protect against such risk.*” 15 U.S.C. § 2608(b)(2) (emphases added).

Although EPA has certain authorities to regulate fluoride in drinking water under the Safe Drinking Water Act (SDWA), there is an important distinction between TSCA and SDWA that permits EPA to take the requested action under TSCA in a more targeted, efficient, and less expensive manner than would be the case under SDWA. Namely, TSCA permits the EPA to differentiate between fluoride that is *added* to water versus fluoride that is *naturally occurring*. As explained in Section XII below, prioritizing regulatory action against fluoridation *additives* is further justified on policy and scientific grounds. It is therefore in the public interest for EPA to take the requested action under TSCA, instead of SDWA.

III. FLUORIDE IN DRINKING WATER: RECENT REGULATORY BACKGROUND

In 2003, the EPA asked the National Research Council (NRC) to review the scientific merits of EPA’s Maximum Contaminant Level Goal (MCLG) for fluoride, which then and now is set at 4 mg/L. In response, the NRC reviewed the existing research on fluoride toxicity and concluded, in March 2006, that the MCLG is not protective of public health and should be lowered. (NRC 2006). The NRC’s conclusion was based on fluoride’s adverse effects on bone and teeth, but the NRC also raised numerous concerns about the potential for fluoride to cause other systemic harm, particularly to the nervous and endocrine systems.

With respect to the nervous system, the NRC concluded: “On the basis of information largely derived from histological, chemical, and molecular studies, it is apparent that fluorides have the ability to interfere with the functions of the brain.” (NRC 2006, at 222). The NRC’s conclusion about fluoride’s interference with the brain rested primarily on its review of animal studies, since—at the time of NRC’s review—few human studies were available. The situation today, however, is much different as many studies linking fluoride exposure to cognitive deficits in humans have now been published. The number of human studies published subsequent to the NRC review that have found significant relationships between fluoride and adverse cognitive outcomes (n = 46) dwarfs the number of such studies that were available to the NRC (n = 5).³

drinking water enables EPA to regulate direct and indirect additives to drinking water as chemical substances and mixtures under TSCA.” (EPA/FDA 1979)

³ The 46 post-NRC human cognitive studies are cited in Appendix A. The five human cognitive studies that NRC cited are: Li et al. (1995); Zhao et al. (1996); Lu et al. (2000); Xiang et al. (2003a,b); and Qin et al. (1990).

The evidence linking fluoride to neurotoxicity in humans, therefore, is far more compelling today than it was when NRC published its review. Indeed, in 2014, fluoride was added to the list of chemicals “*known to cause developmental neurotoxicity in human beings*” in a review published by *Lancet Neurology*. (Grandjean & Landrigan 2014, at 334, Tbl 2). Only 12 chemicals are on this list.

It has been 10 years since the NRC concluded that the MCLG for fluoride be lowered, but the EPA has yet to do so. Further, despite the voluminous post-2006 research on neurotoxicity, and despite the Safe Drinking Water Act’s mandate that EPA protect against “known or *anticipated* adverse effects,”⁴ EPA’s Office of Water (EPA OW) has indicated that it will *not* be considering neurotoxicity as an endpoint of concern when promulgating the new MCLG. Specifically, in its December 2010 risk assessment of fluoride’s non-cancer effects, EPA OW established a reference dose for fluoride based solely on severe dental fluorosis, and declined to add an uncertainty factor to account for the neurotoxicity hazard. (EPA 2010, at 3 & 106). EPA OW justified this decision on the grounds that NRC’s 2006 review did not draw firm conclusions about the public health relevance of fluoride neurotoxicity. (EPA 2010, at 106). Nowhere in EPA OW’s risk assessment, however, did it account for the neurotoxicity research published subsequent to NRC’s review.

The cavalier manner in which EPA’s OW dismissed the evidence of fluoride neurotoxicity stands in stark contrast to EPA’s own *Guidelines for Neurotoxicity Risk Assessment* [hereafter *Guidelines*] that EPA has stated it “*will follow in evaluating data on potential neurotoxicity associated with exposure to environmental toxicants.*” (EPA 1998, at 1). Petitioners submit that application of EPA’s *Guidelines* to the existing database for fluoride shows that neurotoxicity is a hazard of fluoride exposure, that the weight of evidence indicates neurotoxicity is a more sensitive endpoint of fluoride exposure than severe dental fluorosis,⁵ and, further, that the reference dose for fluoride that will protect the public and susceptible subpopulations against neurotoxicity is incompatible with the doses now ingested in fluoridated areas.

IV. FLUORIDE’S NEUROTOXICITY IS SUPPORTED BY OVER 180 STUDIES PUBLISHED SINCE NRC’S 2006 REVIEW

One of the striking features of the research on fluoride neurotoxicity is the large quantity of studies—animal, cellular, *and* human—that have reported an effect. In a recent review of developmental neurotoxins by EPA scientists, only 22% of suspected neurotoxins were found to have *any* supporting human data. (Mundy et al. 2015, at 25). The EPA team thus characterized chemicals, including fluoride, whose suspected neurotoxicity is backed by human data, as “gold standard” chemicals that warrant prioritization. (Mundy et al. 2015, at 27). In the case of fluoride, not only is there human data, the data is so extensive that fluoride has been classified alongside lead, mercury, and PCBs as one of only 12 chemicals “*known to cause developmental neurotoxicity in human beings.*” (Grandjean & Landrigan 2014, at 334, Tbl 2). The existence of so many human studies on fluoride neurotoxicity highlights the urgent need for a diligent risk assessment, per EPA’s *Guidelines*, to ensure that the general public, and sensitive subpopulations, are not ingesting neurotoxic levels.

⁴ 42 U.S.C. § 300g-1(b)(4)(A).

⁵ The *Guidelines* state that: “If data are considered sufficient for risk assessment, and *if neurotoxicity is the effect occurring at the lowest dose level* (i.e., the critical effect), an oral or dermal RfD or an inhalation RfC, based on neurotoxic effects, is then derived.” (EPA 1998, at 2)

Unlike EPA's 2010 risk assessment, a diligent evaluation of fluoride's neurotoxicity would consider the voluminous data that has been released since the NRC published its review in March 2006. Towards this end, Petitioners have attached an exhaustive list of human, animal, and cell studies of fluoride's neurotoxicity that have become available since NRC's review.⁶

In total, Petitioners have identified 196 published studies that have addressed the neurotoxic effects of fluoride exposure subsequent to the NRC's review, including 61 human studies, 115 animal studies, 17 cell studies, and 3 systematic reviews.

The post-NRC human studies include:

- 54 studies investigating fluoride's effect on cognition, including but not limited to IQ, with all but 8 of these studies finding statistically significant⁷ associations between fluoride exposure and cognitive deficits.⁸ (Appendix A)
- 3 studies investigating fluoride's effect on fetal brain, with each of the 3 studies reporting deleterious effects. (Appendix B)
- 4 studies investigating fluoride's association with other forms of neurotoxic harm, including ADHD, altered neonatal behavior, and various neurological symptoms. (Appendix C)

The post-NRC animal studies include:

- 105 studies investigating fluoride's ability to produce neuroanatomical and neurochemical changes, with all but 2 of the studies finding at least one detrimental effect in the fluoride-treated groups. (Appendix D)
- 31 studies investigating fluoride's effect on learning and memory, with all but one of the studies finding at least one deleterious effect in the fluoride-treated groups. (Appendix E)
- 18 studies investigating fluoride's impact on other parameters of neurobehavior besides learning and memory, with all but one of the studies finding effects. (Appendix F)

The post-NRC cell studies include:

- 17 studies, including 2 studies that investigated and found effects at fluoride levels that chronically occur in the blood of Americans living in fluoridated communities. (Appendix G)

⁶ Included among these studies are Chinese language studies that were originally published in Chinese journals prior to 2006 but were not translated and made available in the U.S. until after the NRC's review. Excluded from these studies are those that are only available in abstract form, and animal/cell studies that have not yet been published and/or translated into English.

⁷ In 4 of the 8 studies not finding statistically significant associations, the IQs of the children in the high-fluoride area were lower than in the low-fluoride area. (Eswar et al. 2011; Yang et al. 2008; Fan et al. 2007; Zhang et al. 1998) The 4 studies that did not find any association between fluoride exposure and IQ, significant or otherwise, are: Broadbent et al. 2015; Kang et al. 2011; He et al. 2010; and Li et al. 2010.

⁸ Petitioners are aware of two unpublished fluoride/IQ studies from Mexico, one which reports a significant relationship between prenatal fluoride exposure and reduced IQ (water F = 3.1 mg/L; urine F = 2.0 mg/L) (Rocha Amador et al. 2016), and one which reports no association between childhood IQ and low-level prenatal and postnatal exposures (Thomas 2014). The Thomas study failed to detect an association between IQ and urinary/serum fluoride concentrations in a population with average urinary and serum fluoride levels among pregnant women of 0.89 mg/L and 0.02 mg/L, respectively, and average urinary fluoride concentrations among children of 0.64 mg/L. The Thomas study, however, failed to find a significant correlation between urinary and serum fluoride levels, which raises questions about whether the study's spot-sample testing method reliably reflected the chronic fluoride intake among the cohort.

In addition to the above studies, Petitioners are submitting three post-NRC systematic reviews of the literature, including two that address the human/IQ literature, and one that addresses the animal/cognition literature. (NTP 2016; Choi et al. 2012; Tang et al. 2008).

V. FLUORIDE POSES NEUROTOXIC RISKS AT LEVELS RELEVANT TO U.S. POPULATION

A frequent claim made by those who continue to promote fluoridation is that the doses of fluoride associated with neurotoxicity in humans and animals so vastly exceed the levels which Americans drinking fluoridated water receive as to be entirely irrelevant. In support of this claim, proponents of fluoridation often point to the *highest* levels that have been linked to neurotoxicity, while ignoring the *lowest* levels (and even the *typical* levels) that have been associated with harm.⁹ This focus on the *highest* levels that cause harm as the starting point for analysis, rather than the lowest levels, clashes with standard tenets of risk assessment, including EPA's *Guidelines*, where the starting point for risk characterization analysis is to determine the *Lowest* Observable Adverse Effect Level (LOAEL) or No Observable Adverse Effect Level (NOAEL).¹⁰

A. Fluoride Repeatedly Linked to Reduced IQ at “Safe” Water Fluoride Levels

Contrary to the oft-repeated claim that fluoride neurotoxicity is only found at irrelevantly high doses, the existing studies of fluoride-exposed human populations have consistently found neurotoxic effects at water fluoride levels well below the current MCLG. To help clarify this issue, we examined the IQ studies that were included in the meta-review by Choi, et al. (2012). Proponents of fluoridation have dismissed the relevance of the Choi meta-review on the grounds that the IQ studies it included were in communities with fluoride levels that ranged as high as 11 ppm. As can be seen in the following table, however, the majority of waterborne fluoride studies (i.e., 13 of 18)¹¹ that Choi reviewed included communities with fluoride levels below the 4 mg/L MCLG. Further, each of the 13 studies that investigated the effect of fluoride levels below 4 mg/L (average F = **2.3 mg/L**) found these communities to have a lower average IQ than the control (average reduction = 6.3 IQ points), with the difference reaching statistical significance in 10 of the 13 studies.¹²

⁹ Another common misconception is that the endemic fluorosis/IQ studies prove the safety of fluoridated water because the control populations in these studies often have 0.7 to 1.0 mg/L fluoride in their water. Using areas with 0.7 to 1.0 mg/L as the *control*, however, says nothing about the safety of these levels since they are not compared against communities with *lower* fluoride levels.

¹⁰ As the *Guidelines* note, “Typically, estimates of the NOAEL/LOAEL are taken from the *lowest* part of the dose-response curve associated with impaired function or adverse effect.” (EPA 1998, at 58). Similarly, when the Benchmark Dose (BMD) approach is utilized instead of the NOAEL/LOAEL methods, EPA's point of departure is the low end of the dose-response curve, not the high end.

¹¹ We excluded any waterborne-fluoride exposure studies that did not report the water fluoride levels in the endemic fluorosis area(s). We excluded Li et al. (2010) because it did not compare a high fluoride community against a low-fluoride community, but simply looked at whether children with dental fluorosis in the high-fluoride community (2.5 mg/L) had lower IQ than children without dental fluorosis in the same community. We treated the Wang et al. 2001 and Yang et al. 1994 papers as a single study because it is apparent from the IQ data in the two papers that they are based on the same underlying IQ study. For the 18 qualifying studies, we reviewed the manuscripts to determine the lowest average fluoride concentration in each of the studies that was associated with reduced IQ. In studies with multiple exposure groups (e.g., Yao et al. 1996; Yao et al. 1997), we selected the lowest exposure group that had a reduction in IQ. For studies that only provide a range of fluoride levels for a given exposure group, we selected the midway point in the range to represent the average fluoride concentration for the group.

¹² As set forth in the accompanying table, one of the two studies that failed to find a statistically significant difference in average IQ (Wang et al. 2001) found an “obvious” increase in the rate of children with IQ scores lower than 80 (36.7% vs. 16.7%).

TABLE 1: Water Fluoride Levels and Associated IQ Changes in Studies Reviewed by Choi, et al.		
Study	Water F Level	IQ Change
Zhang et al. 1998	0.8 mg/L	-2.1 ^g
Lin et al. 1991	0.9 mg/L ^Ω	-7.0 ^a
Xu et al. 1994	2.0 mg/L ^Ω	-5.6 ^d
Yao et al. 1996	2.0 mg/L	-3.6 ^d
Yao et al. 1997	2.0 mg/L	-5.1 ^d
Pourleslami et al. 2011	2.4 mg/L	-6.4 ^a
Xiang et al. 2003	2.5 mg/L	-8.2 ^d
Seraj et al. 2006	2.5 mg/L	-11.0 ^b
An et al. 1992	2.7 mg/L	-7.9 ^f
Hong et al. 2001	2.9 mg/L ^Ω	-7.2 ^d
Wang 2001/Yang 1994 [¶]	3.0 mg/L	-5.0 ^h
Lu et al. 2000	3.2 mg/L	-10.9 ^e
Fan et al. 2007	3.2 mg/L	-2.3 ^g
Zhao et al. 1996	4.1 mg/L	-7.5 ^c
Chen et al. 1991	4.6 mg/L	-3.8 ^d
Wang et al. 1996	4.8 mg/L	-5.6 ^a
Wang et al. 2006	5.5 mg/L	-4.1 ^d
Wang et al. 2007	8.3 mg/L	-6.0 ^a
^a p<0.05; ^b p=0.025; ^c p<0.02; ^d p<0.01; ^e p<0.005; ^f Statistical significance not reported; ^g Not statistically significant; ^h Not statistically significant when analyzed in terms of average IQ, but “obvious” difference seen when analyzed in terms of percentage with low IQ; ^Ω High-fluoride + low-iodine versus low-fluoride + low-iodine; [¶] These two papers appear to be the same study.		

Additional studies finding reduced IQ in communities with less than 4 mg/L have become available in the years since Choi’s review, including Sudhir et al. 2009 (**0.7 to 1.2 mg/L**); Zhang S. et al. 2015 (**1.4 mg/L**), Das & Mondal 2016 (**2.1 mg/L**), Choi et al. 2015 (**2.2 mg/L**), Sebastian & Sunitha 2012 (**2.2 mg/L**); Trivedi et al. 2012 (**2.3 mg/L**), Khan et al. 2015 (**2.4 mg/L**); Nagarajappa et al. 2013 (**2.4 to 3.5 mg/L**), Seraj et al. 2012 (**3.1 mg/L**), and Karimzade et al. 2014a,b (**3.94 mg/L**). Another study (Ding et al. 2011), which did not fit within Choi’s dichotomous exposure criteria, found reduced IQ in an area with fluoride levels ranging from **0.3 to 3 mg/L**. In total, there are now 23 studies reporting statistically significant reductions in IQ in areas with fluoride levels currently deemed safe by the EPA (less than 4 mg/L).¹³

B. Fluoride Linked to Cognitive Deficits at Levels of Individual Exposure Seen in Western Fluoridated Populations

Although the water fluoride levels associated with IQ reductions are modestly higher than the levels currently used in artificially water fluoridation programs, it is important to distinguish between the *concentration* of fluoride in a community’s water supply and the *dose* of fluoride that an individual ingests. For example, in rural China (where most of the IQ studies have been conducted), fluoridated toothpaste is rarely used, with less than 10% of children using any fluoride toothpaste at all.¹⁴ By contrast, in the United States, over 95% of toothpastes are fluoridated and research shows that toothpaste can contribute more fluoride to a child’s daily intake than fluoridated water. (CDC 2013c; Zohoori et al. 2013, Zohoori et al. 2012; Levy et al.

¹³ The 23 studies include the 10 studies listed in Table 1, the 11 studies listed in the paragraph above, and the studies by Eswar et al. 2011 and Shivaprakash et al. 2011.

¹⁴ According to a 1996 national oral health survey in China, 75% of 12-year-old children use toothpaste, and of the children who use toothpaste, only 11% use fluoride-containing varieties. (Zhu et al. 2003, at 291, Tbl 1.)

1999). As noted by a review in the *Journal of Public Health Dentistry*, “Virtually all authors have noted that some children could ingest more fluoride from dentrifice alone than is recommended as a total daily fluoride ingestion.”¹⁵ (Levy and Guda-Chowdhury 1999, at 216-17). The abundance of fluoridated toothpaste in the U.S., versus its relative scarcity in rural China, will therefore lessen the difference in total daily fluoride intake between these populations. In fact, as set forth below, available evidence suggests that the (i) daily fluoride doses, (ii) urine fluoride levels, (iii) serum fluoride levels, and (iv) dental fluorosis levels associated with IQ reductions in the Chinese studies are seen in children and adults in western countries living in fluoridated areas. Each of these four metrics of fluoride exposure provide a more direct assessment of individual fluoride exposure than water fluoride concentration, and are thus more probative for risk assessment purposes.

(i) Daily Fluoride Intake

The overlap between the daily fluoride intake associated with significant IQ loss in China and the daily doses American children now receive is highlighted by the recent studies from Wang et al. (2012) and Das et al. (2016). In the study by Wang, researchers investigated the impact of total daily intake of fluoride on IQ among the same group of 512 rural Chinese 8-to-13 year old children studied by the Xiang team in 2003. (Xiang et al. 2003a,b). As the following table shows, the Wang study found a clear dose response relationship between daily fluoride dose and reduced IQ.

FIGURE 1: Relationship Between Daily Fluoride Dose and IQ
(SOURCE: Wang et al. 2012, Tbl. 4)

Wang found that a daily intake of just 2.61 mg F/day was associated with a large, statistically significant 7.28-point drop in *average* IQ. Assuming an average weight of 32 kg,¹⁶ a daily intake

¹⁵ Petitioners recognize that the FDA has jurisdiction over fluoride toothpaste, but any assessment of the safe level of a contaminant in drinking water cannot be conducted in a vacuum, and must consider the additive effect of waterborne exposures with identifiable non-water sources of exposure. When considering the neurologic safety of fluoridated water, therefore, it is critical to consider the aggregate dose of fluoride in fluoridated communities from all sources, including toothpaste. EPA has recognized this principle in its “relative source contribution” analyses, which the EPA OW conducts when calculating the drinking water equivalent level (DWEL) of a reference dose. EPA (2016). TSCA also specifically contemplates consideration of aggregate and sentinel exposures in Section 6 risk evaluations. See 15 U.S.C. § 2605(b)(4)(F).

¹⁶ The authors did not provide data on the average weight of the children in the study, and we could not find data on the average weight of rural Chinese children between the ages of 8 and 13. We did, however, find published data on

of 2.61 mg would provide a dosage of approximately **0.08 mg/kg/day**,¹⁷ which is *lower* than the *average* daily intake (**0.087 mg/kg/day**) for non-nursing infants in the United States, as estimated by the NRC, and just two times greater than the *average* daily dose for 8-12 year old American children.¹⁸ (NRC 2006, at 65, Tbl. 2-13). Moreover, recent research has found that 10 to 15% of children under the age of 6 ingest over 0.05 mg/kg/day *from toothpaste alone*, with some children ingesting as much as **0.159 mg/kg/day** from this single source. (Strittholt et al. 2016 at 70 tbl. 2; Zohoori et al. 2012 at 418 tbl 2; Zohoori et al. 2013 at 460 tbl 1; Levy & Guha-Chowdhury 1999 at 217 tbl 3). In one study, published by Proctor & Gamble scientists (Strittholt et al. 2016), 5% of pre-schoolers were found to ingest at least 0.49 mg fluoride per brushing, which, at two brushings per day, will produce a daily dosage of 0.07 mg/kg/day from toothpaste alone for the average-weighting 2-year-old. (CDC 2000a,b). Other studies are consistent with these estimates. (Oliveria et al. 2007; Bentley et al. 1999; Levy 1993; Naccahe et al. 1992). For the many pre-school children ingesting these dosages from toothpaste, the consumption of fluoridated water will readily push them over the daily dosage (0.08 mg/kg/day) associated with sharp reductions in IQ among rural Chinese children.

Finally, as with other forms of fluoride toxicity, the potential for fluoride neurotoxicity is magnified among children with suboptimal nutrient intake. (Sun et al. 2016; Ge et al. 2011; Hong et al. 2008; Ge et al. 2005; Wang et al. 2004; Ekambaram & Paul 2002; Xu et al. 1994; Lin et al. 1991; Ren et al. 1989; Guan et al. 1988). This is highlighted by the recent study by Das and Mondal which assessed the relationship between fluoride intake and IQ among a population with a high prevalence of underweight children suggestive of an area with pervasive malnutrition. In this population, Das and Mondal confirmed a significant correlation between total fluoride intake and reduced IQ ($r = -0.343$, $p < 0.01$), as plotted in the following figure:

FIGURE 2: Relationship Between Total Daily Intake and IQ
(SOURCE: Das & Mondal 2016, Fig. 6)

the weight of rural Chinese children ages 0 to 7, as well as average weight data on U.S. children between the ages of 2 and 20. (Li et al. 2011; CDC 2000a,b) A comparison of these two datasets shows that rural Chinese children weigh approximately 4 kg less than U.S. children (18.7 kg vs. 23 kg) between the ages of 6 and 7. We thus determined the average weight of 8-to-13 year old rural Chinese children by calculating the average weight of 8-to-13 year old U.S. from the CDC growth charts (=36 kg) and subtracting 4 kg (=32 kg).

¹⁷ It bears noting that 0.08 mg/kg/day is EPA's new reference dose for fluoride, which the Agency established to protect solely against severe dental fluorosis (without the protection of a single uncertainty factor to account for potential neurotoxic risks). (EPA 2010)

¹⁸ A recent national analysis of urinary fluoride levels in the United Kingdom UK concluded that over 65% of adults living in fluoridated areas consume more than 0.057 mg/kg/day. (Mansfield 2010)

Notably, Das and Mondal found a sharp 15-point drop in IQ among underweight children with *mild* dental fluorosis who were consuming average total daily fluoride exposures of just **0.06 mg/kg/day**. (Das & Mondal 2016, at 218, Tbl. 3). As discussed above, this is a dose that many infants and children in the U.S. are estimated to exceed.

(ii) Urine Fluoride Level

Many of the studies on fluoride and IQ have measured the concentration of fluoride in children's urine as a marker of individual fluoride exposure. As summarized in a 2011 review, these studies have repeatedly found significant, often large reductions in IQ when the average urinary fluoride level exceeds 2.5 mg/L, (Spittle 2011), and multiple regression analyses have repeatedly found that increased urinary fluoride correlates with reduced IQ, (Das et al. 2016; Zhang S. et al. 2015; Wang et al. 2007), even when controlling for other key risk factors. (Rocha Amador et al. 2009). While urinary fluoride levels exceeding 2.5 mg/L present a clear risk for neurotoxicity, recent studies have also found decrements in IQ at urinary fluoride concentrations well below this level. Most notable in this regard is the study by Ding et al., which examined the correlation between urinary fluoride and IQ among children with urinary fluoride levels ranging from just 0.25 mg/L to 3 mg/L. As shown in the following figure, a clear dose response trend was found within this urinary fluoride range ($p < 0.0001$), with the downward trend becoming apparent at roughly 1 mg/L. When adjusted for age, each 1 mg/L increment in urinary fluoride correlated with an average drop of 0.59 IQ points ($p < 0.0001$).

FIGURE 3: Relationship Between Urinary Fluoride and IQ
(SOURCE: Ding et al. 2011, Fig. 2)

The dose-response trend found by Ding is consistent with more recent data published by Zhang et al. 2015, which is displayed in the following figure. As can be seen, the Zhang study found a clear drop in IQ at urinary fluoride levels between 0.5 and 1.5 mg/L.

FIGURE 4: Relationship Between Urinary Fluoride and IQ
(SOURCE: Zhang S. et al. 2015, Fig. 1)

More recently, researchers have investigated the prevalence of cognitive impairment among elderly individuals living in an endemic fluorosis region of China. (Li et al. 2016). The researchers found a very high prevalence of cognitive impairment (81.2%) in the fluorosis region, and, in a case-control analysis, found a significantly elevated urinary fluoride level (2.5 mg/L vs. 1.5 mg/L, $p < 0.05$) in the cognitive impairment group.¹⁹ (Li et al. 2016, at 57, Tbl. 3). The data from this case-control analysis is presented in the following table:

TABLE 2: Urinary Fluoride & Cognitive Impairment in Elderly
(SOURCE: Li et al. 2016, Tbl 3)

Characteristics ^a	Normal group (n=38)	Cognitive impairment group (n= 38)	P value
Male/female	26/12	26/12	
Age (years)	64.95±4.60	65.05±4.40	0.920
MMSE score	27.79±0.96	21.50±4.37	0.000
Total daily water fluoride intake(mg ^b)	2.23±2.23	3.62±6.71	0.228
Urinary fluoride(mg/L ^b)	1.46±1.04	2.47±2.88	0.046
fluorosis score ^b	0.74±0.98	1.29±1.01	0.018
Serum Hcy(μmol/L ^b)	19.97±8.88	20.14±9.29	0.934

^a Values are n/n for gender and mean±SD for other indices.

^b The original values were log-transformed before comparison. The difference between two groups was tested using Student's t test.

Although there is a paucity of published data on urinary fluoride levels in the United States, a study from England found that the average urinary fluoride level among 88 adults living in a fluoridated area was 1.28 mg/L, with 16% of the tested individuals having over 2 mg/L, and 6%

¹⁹ A clear dose-response relationship between urinary fluoride and cognitive impairment was not detected in the non-case control component of Li et al.'s analysis, although urinary fluoride was found to be elevated in the population with severe cognitive impairment.

of individuals having over 3 mg/L.²⁰ (Mansfield 1999, at 28, Tbl. 1). These levels overlap those that have been associated in endemic fluorosis areas with both reduced IQ in children and cognitive impairment in the elderly. (Li et al. 2016; Zhang S. et al. 2015; Ding et al. 2011). A more recent study from Canada found that 5 percent of *children* had ≥ 1.3 mg/L fluoride in their urine, which is well within the range of urinary fluoride levels associated with reduced IQ in the Ding and Zhang studies. (Saravanabhavan et al. 2016). A separate Canadian study found that the *average* urinary fluoride concentration in fluoridated areas was 0.76 mg/L, which was almost twice the concentration (0.47 mg/L) found in non-fluoridated areas. (McLaren 2016).

(iii) Serum Fluoride Level

In 2011, Xiang et al. published a paper which assessed the relationship between IQ and serum fluoride levels in the same group of 512 children studied in Wang's daily dose analysis discussed above. As with the daily dose analysis, the authors found a significant dose-response relationship between serum fluoride level and reduced IQ. As shown in the following table, children with just 0.05 to 0.08 mg/L fluoride in their serum had a statistically significant 4.2-point drop in IQ when compared against children with less than 0.05 mg/L.²¹

TABLE 3: Association Between Serum Fluoride and Children's IQ
(SOURCE: Xiang et al. 2011, Tbl 2)

Serum fluoride level quartiles	N	Mean IQ	SD IQ	p ^b	IQ<80 (%)	p ^c	OR (95% CI) for IQ<80
Q1 and Q2 (<0.05 mg/L)	259	100.1	13.4	<0.001	7.0		1
Q3 (0.05–0.08 mg/L)	126	95.9	13.7		15.1	0.004	2.22 (1.42–3.47)
Q4 (>0.08 mg/L)	127	92.1	13.4		17.3		2.48 (1.85–3.32) p trend<0.001 ^d

The Xiang team's findings are consistent with the findings of other recent studies, including Guo Z. et al. (2008), which found impairment in neurobehavioral function among adult industrial workers with average serum fluoride levels of 0.066 mg/L, and Zhang S. et al. (2015), which found significant reductions in IQ among children with just over 0.05 mg/L fluoride in their blood when compared to children with the lowest levels. The Zhang study plotted the serum data in the following figure:

²⁰ These urinary fluoride levels exceeded those that were found among individuals (n = 165) living in non-fluoridated areas. The average urinary fluoride level in the non-fluoridated areas was 0.96 mg/L; with 8% having more than 2 mg/L; and 4% having more than 3 mg/L. (Mansfield 1999, at 28, Tbl. 1)

²¹ As the authors emphasize, their finding of a 4-point IQ drop in children with more than 0.05 mg/L fluoride in their serum does *not* mean that serum levels lower than 0.05 mg/L are safe.

FIGURE 5: Relationship Between Serum Fluoride and IQ
(SOURCE: Zhang S. et al. 2015, Fig. 1)

To put these serum fluoride levels in the context of U.S. exposures, typical serum fluoride levels for adults in the U.S. have been stated to range from about 0.01 to 0.076 mg/L (0.5 to 4 uM/L). (CDC 2014, at 2; see also Kissa 1987). In one study of infants, an average concentration of 0.08 mg/L was found among healthy 4-to-6 month old infants, while an average concentration of 0.10 to 0.18 mg/L was found among 4-to-18 month old infants receiving peritoneal dialysis. (Warady et al. 1989). A study by Ekstrand found that infants ingesting 0.25 mg in supplement form have spikes in their blood ranging as high as 0.092 mg/L, and averaging 0.063 mg/L. (Ekstrand 1994, at 159 tbl 3). Ekstrand's study did not measure the impact of ingesting fluoride in the form of infant formula reconstituted with fluoridated water, but the resulting daily peaks in serum fluoride levels may be comparable, since Ekstrand estimates that infants consuming fluoridated formula receive doses (up to five times a day) that are comparable to a supplement (i.e., 20-30 ug/kg of fluoride per formula feeding vs. 32 ug/kg per supplement). (Ekstrand 1994, at 162).

While there has long been a paucity of serum fluoride data available for children in the U.S., a recent NHANES survey found that roughly 1 in 200 American children between the ages of 3 to 19 have serum fluoride levels exceeding 0.04 mg/L. (NHANES 2016). Since there are approximately 70 million American children in this age range, (US Census Bureau 2011), the NHANES data indicates that approximately 350,000 American children have serum fluoride levels in the approximate range associated with overt neurotoxic effects.

(iv) Dental Fluorosis Level

EPA OW's 2010 risk assessment of the non-cancer effects of fluoride rests on the implicit assumption that *severe* dental fluorosis is the most sensitive adverse endpoint of fluoride exposure. This assumption, however, is at odds with a number of studies which have found significant associations between fluoride exposure and cognitive deficits among children with *non-severe* forms of fluorosis. Most notably, the study by Ding et al. (2011) found a dose-dependent relationship between reduced IQ and urinary fluoride concentration in a population where severe dental fluorosis was *completely absent*. The Ding study thus suggests that the doses of fluoride that impair cognitive ability are lower than the doses that cause severe fluorosis. Other recent studies have found impairment in cognitive abilities among children with *mild* fluorosis, *moderate* fluorosis, and *moderate/severe* fluorosis when compared with children with no fluorosis, thus suggesting that the doses of fluoride associated with the milder forms of

fluorosis are sufficient to impair brain development.²² (Das & Mondal 2016 at tbl 3; Choi et al. 2015; Li et al. 2009; Khan et al. 2015; Shivaprakash et al. 2011; Sudhir et al. 2009 at tbl 3).

Consistent with the above studies of human populations, studies of rodents have repeatedly found significant impairments in learning ability as well as other neurotoxic harms among rats with only mild forms of fluorosis.²³ (Liu et al. 2011; Pereira et al. 2011; Niu et al. 2008; Chioca et al. 2008). As noted by Niu et al., “these findings indicate that fluoride . . . can influence spontaneous behaviors and lower the learning ability of rats before the appearance of dental lesions.”²⁴ (Angmar-Mansson & Whitford 1982).

Taken together, the available human and animal studies suggest that fluoride can impair cognitive abilities prior to the development of severe fluorosis. This has obvious public health relevance in the United States, since recent studies show that the prevalence of dental fluorosis is now at historically unprecedented levels. In CDC’s 1999-2004 NHANES survey, for example, 41% of adolescents were diagnosed with dental fluorosis, including 8.6% with mild fluorosis, and 4% with moderate and severe. These rates are considerably higher than what was found in the 1986-87 national survey by the National Institute of Dental Research. (Beltran et al. 2010; Heller et al. 1997). Moreover, the rates appear to have increased yet further since the 1999-2004 NHANES survey. Specifically, the 2011-2012 NHANES survey found dental fluorosis in 58.3% of the surveyed adolescents, including an astonishing 21.2% with moderate fluorosis, and 2% with severe. (NHANES 2014). Since there are an estimated 42 million adolescents currently living in the U.S.,²⁵ the NHANES data suggests that up to 24 million adolescents now have some form of dental fluorosis, with over 8 million adolescents having moderate fluorosis, and 840,000 having severe fluorosis.

The NHANES surveys do not provide data on the respective rates of fluorosis in fluoridated vs. non-fluoridated communities, but research has repeatedly confirmed that both the prevalence and severity of dental fluorosis are greater in U.S. communities with fluoridated water than in communities without. (Heller et al. 1997; Jackson et al. 1995; Williams & Zwemer 1990). Ending fluoridation will thus reduce the number of children developing dental fluorosis, and the accompanying neurotoxic risks associated with the doses that produce fluorosis.²⁶

²² Some studies, however, including Ding, have not found a clear relationship between IQ and dental fluorosis status, thus suggesting that a person’s susceptibility to fluoride-induced neurotoxicity may be distinct from their susceptibility to dental fluorosis. (Asawa et al. 2014; Li et al. 2010)

²³ Consistent with this, Zhou Z. et al. (2016) recently reported that biochemical changes occur in rats at doses well below those that cause dental fluorosis.

²⁴ While rodent teeth undergo constant remodeling, thus distinguishing them from human teeth, research has found that rat teeth develop dental fluorosis at the same serum fluoride levels that produce fluorosis in humans. According to Angmar-Mansson & Whitford, “It is well known that, in fluoridated drinking water studies with rats, a water fluoride concentration of 10-25 ppm is necessary to produce minimal disturbances in enamel mineralization. Because of the high water concentrations required, the rat has been regarded as more resistant to this adverse effect of fluoride. However, when the associated plasma levels are considered, the rat and the human appear to develop enamel fluorosis at very nearly the same concentrations.” (Angmar-Mansson & Whitford 1982, at 339) Based on this finding, Angmar-Mansson & Whitford concluded that “the rat is a better model for the study of human enamel fluorosis than previously believed.” (*Id.* at 334)

²⁵ This estimate is based on the number of Americans between the ages of 10 and 19. It comes from the Office of Adolescent Health, which is part of the Department of Health & Human Services. (DHHS 2016).

²⁶ Decreases in dental fluorosis have been documented following temporary suspensions of fluoridation as short as 11 months. (Burt et al. 2000)

VI. NEUROTOXIC RISK OF LOW DOSE FLUORIDE IS FURTHER SUPPORTED BY ANIMAL AND CELL STUDIES

The studies linking fluoride exposure with neurotoxic effects in humans are consistent with research on both experimental animals and cell cultures. Studies on rodents, for example, have found neurotoxic effects, including learning impairments, at water fluoride levels less than 15 mg/L, with 8 studies published since the NRC review reporting neurotoxic effects at water fluoride levels less than 5 mg/L. These are notably low fluoride levels for rodents, since it is generally estimated that rats require approximately 5 times more fluoride in their water to achieve the same level of fluoride in their blood as humans, and over 10% of children living in fluoridated areas receive the same waterborne dosage of fluoride (mg/kg/day) as rats drinking water with up to 9 mg F/L. (NTP 2016, at 56-57)

The following table lists the water fluoride concentrations associated with neurotoxic effects in rodents:

Study	F Concentration (F-)	Duration of Treatment	Effects
Chouhan (2010)	1 mg/L	4 months	Oxidative stress; alterations in neurotransmitters
Wu (2008)	1 mg/L	Gestation	Behavioral alterations
Gao (2009)	2.3 mg/L	6 months	Enzyme inhibition; impaired cognition; oxidative stress
Liu (2014)	2.3 mg/L	1 month	Impaired learning
Liu (2010)	2.3 mg/L	6 months	Impaired cognition; alterations in neurotransmitters
Sandeep (2013)	2.3 mg/L	3 months	Behavioral alterations; enzyme inhibition
Zhang (2015)	2.3 mg/L	6 months	Oxidative stress; activation of AGE/RAGE system
Zhang Z. (2008)	4.5 mg/L	10 weeks	Impaired learning; pathological changes in synaptic structure
Zhu (2011); Zhang (2011); Zhang J. (2013)	6.8 mg/L	9 months	Trend towards decreased synaptic membrane fluidity & PSD-95 expression level; altered expression of CaMKII α , c-fos, Bax, and Bcl-2 (statistically significant at 13.6 mg/L)
Bhatnagar (2011)	8 mg/L	1 month	Morphological changes in neurons
Banala (2015)	9 mg/L	Gestation + 30 days postnatal	Impaired learning; loss of motor control; & oxidative stress
Reddy (2014)	9 mg/L	3 months	Alterations in neurotransmitters; altered immunological parameters; oxidative stress
Lou (2014); Lou (2013)	10 mg/L	6 months	Increase in apoptotic neurons; altered expression of Bax and Bcl-2 at protein & mRNA levels; abnormal mitochondrial dynamics
Sun (2008)	10 mg/L	6 months	Impaired learning; increased ChE
Han (2014)	11 mg/L	6 months	Trend towards impaired learning (Fig 2a)
Zhou (2014)	11.3 mg/L	6 months	Altered expression levels of cytokines in hippocampus
Guner (2016)	13.6 mg/L	Gestation + Postnatal	Increased catalase immunoreactivity

Fluoride's ability to cause neurotoxic effects at low levels of exposure is further corroborated by in vitro cell studies conducted subsequent to the NRC review. While most of the in vitro studies

used high levels of fluoride (≥ 10 mg/L), two of the studies investigated the effects of concentrations that are found in the bloodstream of many Americans.²⁷ Both of these low-concentration studies detected adverse effects. As displayed in the following figure, Gao et al. (2008) found that just 0.5 μ M of fluoride (i.e., 0.009 mg/L) caused lipid peroxidation in SH-SY5Y cells after 48 hours of exposure. Most individuals living in fluoridated areas in the United States have fluoride levels in their blood that exceed this level. (CDC 2014; Kissa 1987).

FIGURE 6: Level of Lipid Oxidation in SH-SY5Y Cells Exposed to Fluoride
(SOURCE: Gao et al. 2008, Fig. 1)

The Gao study also found that 0.5 μ M had an effect on the level of $\alpha 7$ nAChR protein in the SH-SY5Y cells, as displayed in the following figure:

FIGURE 7: Level of $\alpha 7$ nAChR subunit protein in SH-SY5Y Cells Exposed to Fluoride
(SOURCE: Gao et al. 2008 Fig. 3)

²⁷ Consistent with the findings of these two brain cell studies, the in vitro studies by Gutowska have repeatedly found that concentrations of just 1 to 3 μ M (i.e., 0.019 to 0.057 mg/L) are sufficient to affect inflammatory responses. (Gutowska et al. 2015, 2012, 2010). The Gutowska team's findings underscore the biologically active nature of even micromolar concentrations of fluoride, and warrant consideration for their implications to neuroinflammation. (Louveau et al. 2011).

Flores-Mendez et al. (2014) also investigated the effect of 0.5 μM , and, per the following figure, found a suggestive trend towards an increase in eEF2 phosphorylation in cultured Bergmann glia cells (BGC) after 15 minutes of treatment.

FIGURE 8: eEF2 Phosphorylation in BGC Cultures Treated with Fluoride
W(SOURCE: Flores-Mendez et al. 2014., Fig. 4b)

Flores-Mendez also found a suggestive trend towards an increased influx of calcium into the cell after 3 minutes of treatment with 5 μM fluoride (i.e., 0.095 mg/L). (Flores-Mendez et al. 2014, at 130 Fig. 5c) This concentration can be found chronically in the blood of children with kidney disease living in fluoridated areas, (Warady et al. 1989), and is intermittently exceeded by children ingesting fluoride supplements, fluoridated toothpaste, and other dental products.²⁸

VII. RECENT EPIDEMIOLOGICAL STUDIES CORROBORATE NEUROTOXIC RISK FROM FLUORIDATED WATER IN WESTERN POPULATIONS

The overlap between the internal doses of fluoride experienced in western populations and the internal doses associated with neurotoxic effects in humans, animals, and cell cultures, is cause for public health concern. Although there has been a notable lack of epidemiological research into fluoride's neurotoxic effects in the U.S., a 2015 study by Malin and Till found a statistically significant correlation between the prevalence of water fluoridation at the state level and Attention-Deficit Hyperactivity Disorder (ADHD). Fluoridation prevalence significantly correlated with ADHD even after controlling for socioeconomic status (SES), and fluoridation "appeared to be the more robust predictor." As Malin and Till note, their findings "are consistent with prior epidemiological studies that have associated high and low fluoride concentration exposure with neurodevelopmental effects in children."

²⁸ While there is a paucity of research on the serum fluoride levels following use of fluoride tablets and toothpaste, Ekstrand found that, among a group of 5 preschool children, ingestion of 0.5 mg fluoride tablets caused serum fluoride levels to spike to 0.095 mg/L in 30 minutes, while ingestion of 0.6 mg fluoride in toothpaste caused serum fluoride levels to exceed 0.08 mg/L. (Ekstrand et al. 1983, Fig. 1). Since some preschool children swallow considerably more than 0.6 mg fluoride per brushing, the serum fluoride levels will likely be higher than 0.08 mg/L in those children. Levy & Guha-Chowdhury, for example, cite research showing that 10% of preschool children swallow in excess of 0.73 mg of fluoride per brushing. (Levy & Guha-Chowdhury 1999, Tbl. 3).

Another epidemiological study from 2015, by Peckham et al., provides further corroborative evidence that fluoridation can cause neurotoxic effects. Peckham's study examined the relationship between water fluoride levels and hypothyroidism in the United Kingdom, and found that fluoride levels ≥ 0.7 mg/L significantly correlated with higher rates of hypothyroidism. This correlation was strengthened, not weakened, when controlling for the covariates of age, gender, and index of deprivation.

The correlation between fluoridation and hypothyroidism reported by Peckham is (i) plausible and (ii) adds further support for the capacity of fluoridated water to cause neurotoxic effects. First, the correlation is plausible because, as summarized by the NRC, multiple lines of research indicate that fluoride can lower thyroid function, including the fact that fluoride was once used as a drug for this precise purpose, at doses as low as 2 to 5 mg/day. (NRC 2006; Galletti & Joyet 1958). Second, the correlation between fluoridation and hypothyroidism adds further support for fluoridation's neurotoxic potential because, as recognized in EPA's *Guidelines*, "the development of the nervous system is intimately associated with the presence of circulating hormones such as thyroid hormone." (EPA 1998, at 50). Since both clinical and subclinical hypothyroidism during pregnancy have been associated with reduced IQ in offspring, (Korevaar et al. 2016; Murphy et al. 2015; Klein et al. 2001), the relationship between fluoridation and hypothyroidism provides a mechanism by which fluoridation can reduce IQ, even absent a direct neurotoxic effect.

VIII. SUSCEPTIBLE SUBPOPULATIONS ARE AT HEIGHTENED RISK OF FLUORIDE NEUROTOXICITY AND NEED PROTECTION

EPA's *Guidelines* recognize that individual susceptibility to the neurotoxicity of environmental toxicants can vary by a factor of ten or more,²⁹ and is influenced by factors such as nutritional status, age, genetics, and disease. (EPA 1998, at 63-65, 78). Each of these factors—nutritional status, age, genetics,³⁰ and disease—are known to influence an individual's susceptibility to chronic fluoride toxicity.³¹ Any factor that can predispose an individual to chronic fluoride toxicity should be suspected as a factor that will predispose to fluoride neurotoxicity as well. In fact, recent research in both humans and animals has specifically demonstrated that nutrient deficiencies (i.e., iodine³² and calcium³³) amplify fluoride's neurotoxicity.³⁴ Further, Zhang S. et al. (2015) reported that certain COMT gene polymorphism

²⁹ "In general, it is assumed that an uncertainty factor of 10 for intrapopulation variability will be able to accommodate differences in sensitivity among various subpopulations, including children and the elderly. However, in cases where it can be demonstrated that a factor of 10 does not afford adequate protection, another uncertainty factor may be considered in conducting the risk assessment." (EPA 1998, at 65)

³⁰ Studies have repeatedly confirmed that genetic factors can significantly increase susceptibility to fluoride toxicity, (Everett 2011), including effects on bone (Kobayashi et al. 2014; Yan et al. 2007; Mousny et al. 2006); teeth (Buzalaf et al. 2014; Ba et al. 2011; Huang et al. 2008; Everett et al. 2002); and reproductive hormones (Zhou et al. 2016).

³¹ See, e.g., Irigoyen-Camacho ME et al. (2016); Simon et al. (2014); Ravula et al. (2012); Itai et al. (2010); Schiffli (2008); NRC (2006); Teotia et al. (1998); Torra et al. (1998); Warady et al. (1989); and Turner et al. (1995). For additional citations and discussion, see http://www.fluoridealert.org/studies/skeletal_fluorosis03.

³² See, e.g., Ge et al. (2011); Hong et al. (2008); Ge et al. (2005); Wang et al. (2004); Xu et al. (1994); Lin et al. (1991); Ren et al. (1989); Guan et al. (1988).

³³ Sun et al. (2016); Ekambaram & Paul (2002).

³⁴ As discussed earlier, the study by Das & Mondal (2016) examined the impact of fluoride on IQ in a population with a high prevalence of underweight children, suggestive of an area with chronic malnutrition. In this population, a daily fluoride dose of just 0.06 mg/kg/day was associated with a sharp 15-point drop in IQ among children with mild fluorosis. (Das & Mondal 2016, at 218, Tbl. 3).

greatly influences the extent of IQ loss resulting from fluoride exposure, which is consistent with research on other neurotoxins, including methyl mercury. (Julvez & Grandjean 2013).

While the full range of individual susceptibility to fluoride neurotoxicity in the U.S. cannot be precisely calculated, some subpopulations can be identified as being at elevated risk, including infants,³⁵ the elderly,³⁶ and individuals with (A) deficient nutrient intake (particularly iodine and calcium),³⁷ (B) certain COMT gene polymorphisms,³⁸ and (C) kidney disease.³⁹ Various factors suggest that African Americans may also suffer disproportionate risks as well, including elevated use of infant formula,⁴⁰ elevated exposure to lead,⁴¹ depressed calcium and anti-oxidant intake,⁴² and significantly higher rates of dental fluorosis, including in its moderate and severe forms.⁴³

³⁵ Although *breast fed* infants receive the lowest fluoride intake by bodyweight (<0.001 mg/kg/day) of all age-groups (Ekstrand et al. 1981), this situation is flipped on its head when infants are fed *formula reconstituted with fluoridated water*. As noted by the NRC, “On a per-body-weight basis, infants and young children have approximately three to four times greater exposure than do adults.” (NRC 2006, at 3). Not only do formula-fed infants receive an unnaturally high dose, they have an impaired ability to excrete the fluoride they ingest, retaining up to 87% of the absorbed dose. Ekstrand et al. (1994). Infants exposed to formula made with fluoridated water are at significantly higher risk for developing dental fluorosis on their permanent front teeth. Hong et al. (2006). In light of the research linking dental fluorosis and modest levels of fluoride exposure with reduced IQ, infants are a susceptible subpopulation of critical concern for fluoride neurotoxicity.

³⁶ As noted in the *Guidelines*, “[T]he aged population is considered to be at particular risk [of neurotoxicity] because of the limited ability of the nervous system to regenerate or compensate to neurotoxic insult.” (EPA 1998, at 65). This is of concern because the brain will be more exposed to fluoride in older age due to the (1) increased level of fluoride circulating in the serum from both age-related decreases in renal function and age-related increases in bone resorption (particularly in post-menopausal women), and (2) increased permeability of the blood-brain barrier. Rosenberg (2014); Ravula et al. (2012); Itai et al. (2010); Torra et al. (1998). This may help explain the very high prevalence of cognitive impairment (82%) found among elderly individuals in an endemic fluorosis area. Li et al. (2016); see also Shao et al. (2003).

³⁷ According to a consensus paper in the *Journal of the National Medical Association*, “Eighty-six percent of African Americans get just more than half of the daily recommended amount of calcium, and only half consume one or more servings of dairy a day. Of particular concern, 83% of African-American children 2-17 years of age are not getting enough calcium.” Wooten & Price (2004). Insufficient nutrient intakes in the United States are severe enough in some individuals to qualify as nutrient deficiencies. Recent NHANES data, for example, found that 6% of Americans have a vitamin C deficiency. CDC (2012). Vitamin C deficiency has been found to exacerbate fluoride’s toxicity in humans, while vitamin C supplementation has been found to ameliorate fluoride’s neurotoxic effects in animals. Nabavi et al. (2013); Basha & Madhusudhan (2010); Pandit et al. (1940). With respect to iodine, NHANES data shows that women of *child bearing* age (20 to 39 years old) have “median urine iodine concentrations bordering on insufficiency.” Pfeiffer et al. (2013). Children born to women with insufficient iodine levels should be considered a susceptible subpopulation for fluoride neurotoxicity due to fluoride’s ability to exacerbate the neurological effects of inadequate iodine.

³⁸ The study by Zhang S. et al. (2015) suggests that children with the COMT val/val genotype suffered a five-fold larger drop in IQ than children with the COMT val/met and met/met genotypes. As noted by Zhang, “In the subpopulation carrying the COMT reference genotype (Model 3), 1 unit increase in urinary fluoride (1 mg/l) was associated with a decrease of 9.67 points of IQ and was significant after controlling for covariates (P=0.003). Among children carrying variant genotypes, 1 unit increase in [urinary fluoride] resulted in a decrease of 1.85 IQ points, but this was not statistically significant in this stratum.”

³⁹ See, e.g., Schiffi (2008); Ibarra-Santana et al. (2007); Torra et al. (1998); Warady et al. (1989).

⁴⁰ In national surveys conducted between 2000 and 2008, “Black infants consistently had the lowest rates of breastfeeding initiation and duration across all study years.” CDC (2013b).

⁴¹ It is well established that non-Hispanic black children have higher levels of lead in their blood than non-Hispanic white children. CDC (2013a); Bernard & McGheein (2003). This has relevance to the risks of fluoride exposure, since animal studies have found that fluoride can exacerbate the toxicity of lead, and vice versa. Leite et al. (2011); Sawan et al. (2010); Mahaffey & Stone (1976).

⁴² Watters et al. (2007); Wooten & Price (2004). The reduced level of anti-oxidants found in the blood of African American adults, which may relate to low consumption of fresh fruits and vegetables (Zenk et al. 2005), has implications for fluoride toxicity, because oxidative stress is a key mechanism by which fluoride harms cells, (Barbier 2010), including in the brain. (E.g., Banala & Karnati 2015; Zhang K. et al. 2015; Basha et al. 2014; Nabavi et al.

Any risk assessment on the neurotoxicity of fluoride must thus be mindful of the need to protect susceptible subpopulations; anything less would be inconsistent with EPA's *Guidelines*. In fact, even where there is *no* specific information to indicate differential susceptibility to a neurotoxin, EPA's *Guidelines* state that a margin of safety (i.e., "uncertainty factor") should still be incorporated to account for "*potential* differences in susceptibility." (EPA 1998, at 78). In the case of fluoride, there is *uncontroverted* evidence indicating substantial differences in susceptibility, and thus the basis for applying an uncertainty factor is especially strong.

IX. A REFERENCE DOSE PROTECTIVE AGAINST FLUORIDE NEUROTOXICITY IS INCOMPATIBLE WITH WATER FLUORIDATION IF STANDARD RISK ASSESSMENT PROCEDURES ARE APPLIED

As recognized in EPA's *Guidelines*, it is standard risk assessment practice to apply "uncertainty factors" (UF) of 10 when converting a LOAEL, NOAEL, or BMD into a safe "reference dose" (RfD) or "reference concentration" (RfC). (Martin et al. 2013) This is significant because application of even a single UF of 10 to the daily doses/concentrations of fluoride associated with neurotoxic harm in humans and animals produces an RfD or RfC that is less than, and thereby *incompatible with*, the levels of fluoride added to water for fluoridation (0.7 to 1.2 mg/L). This point is illustrated in the following table, which shows what the RfD and RfC would be if *merely* one UF of 10 was applied to the various fluoride exposures that have been associated with neurotoxic harm.

TABLE 5: RfCs/RfDs for Fluoride If Just One Uncertainty Factor of 10 Is Applied				
Fluoride Dose/Concentration Producing Harm	Study	Effect	RfD/RfC After Application of one UF	Water Fluoridation Doses/Concentrations
0.06 mg/kg/day (Dose/Humans)	Das (2016)	Reduced IQ	0.006 mg/kg/day	0.03 to 0.09 mg/kg/day (Average Total Daily Dose in F areas) (NRC 2006, Tbl 2-13)
0.08 mg/kg/day (Dose/Humans)	Wang (2012)	Reduced IQ	0.008 mg/kg/day	0.03 to 0.09 mg/kg/day (Average Total Daily Dose in F areas) (NRC 2006, Tbl 2-13)
1 mg/L (Water/Rats)	Chouhan (2010); Wu (2008)	Behavioral alterations; Neurochemical changes	0.1 mg/L	0.7 to 1.2 mg/L (Water F Levels in F areas)
0.7 to 1.2 mg/L (Water/Humans)	Malin (2015); Peckham (2015)	Hypothyroidism; ADHD	0.07 to 0.12 mg/L	0.7 to 1.2 mg/L (Water F Levels in F areas)
0.7 to 1.2 mg/L (Water/Humans)	Sudhir (2009)	Reduced IQ	0.07 to 0.12 mg/L	0.7 to 1.2 mg/L (Water F Levels in F areas)

2013; Nabavi et al. 2012a,b,c; Basha et al. 2011; Inkielewicz-Stepniak & Czarnowski 2011; Nabavi et al. 2011; Bharti & Srivastava 2009; Gao et al. 2009).

⁴³ Studies dating back to the 1960s have found that African Americans suffer higher rates of dental fluorosis than Caucasians. Martinez-Mier & Soto-Rojas 2010; Beltran-Aguilar et al. (2015, tbl. 23); Kumar (2000); Williams & Zerner (1990); Butler et al. (1985); Russell (1962). Consistent with this, documents obtained through the Freedom of Information Act show a stark racial disparity in adolescent fluorosis rates in CDC's 1999-2004 NHANES survey, with 58% of African American adolescents diagnosed as having the condition, versus 36% of white adolescents. FOIA (2011).

2.3 mg/L (Water/Rats)	Gao (2009); Liu (2014); Liu (2010); Sandeep (2013); Zhang K (2015)	Impaired learning; Behavioral alterations; Neurochemical changes	0.23 mg/L	0.7 to 1.2 mg/L (Water F Levels in F areas)
2.3 mg/L (Water/Humans)	The average water F concentration in the 13 studies reviewed by Choi (2012) which found effects at < 4 mg/L	Reduced IQ	0.23 mg/L	0.7 to 1.2 mg/L (Water F Levels in F areas)
0.05 mg/L (Serum/Humans)	Xiang (2011)	Reduced IQ	0.005 mg/L	0.019 to 0.076 mg/L (Typical range of Serum F in US) (CDC 2014)

The need to apply *at least* one UF to the doses/concentrations associated with fluoride neurotoxicity cannot seriously be disputed. After all, these are doses and concentrations associated with overt neurotoxic harm, and thus the safe reference dose will obviously need to be set at a lower level. Moreover, as discussed above, EPA's *Guidelines* recognize that there is often a large degree of intra-species variability in the way humans respond to neurotoxins and a default factor of 10 is generally considered necessary to protect against this variability.⁴⁴

Although we have only utilized one uncertainty factor in the analysis here, we do *not* mean to imply that only one UF is sufficient for converting these adverse effect levels into RfDs or RfCs. Indeed, it is clearly insufficient to apply only one UF when converting a LOAEL from an animal study into a safe dose for humans. We present the above Table, therefore, for the limited purpose of demonstrating that *even if* EPA were to apply an *insufficiently* protective UF, the resulting RfD or RfC would still be incompatible with water fluoridation; thus highlighting, once again, the overlap between the doses associated with a neurotoxic risk and the doses many Americans now receive.

Finally, Petitioners recognize that EPA has a preference for utilizing Benchmark Dose (BMD) methodology for risk assessments where there is dose-response data that permits the analysis. In the case of fluoride neurotoxicity, the Xiang dataset is a suitable dataset for conducting a BMD analysis, as it shows a dose-related reduction in IQ spanning five dose groups ranging from 0.75 to 4.5 mg F/day without an apparent NOAEL. (Wang et al. 2012). EPA's *Guidelines* recognize the probative value (and rarity) of a human dataset covering more than three dose groups.⁴⁵ Further, the Xiang dataset benefits from the fact that the study controlled for most of the key confounding factors, including lead, arsenic, iodine, parental education, and socioeconomic status. (Xiang et al. 2003a,b; Xiang et al. 2013).

⁴⁴ According to the *Guidelines*, "In general, it is assumed that an uncertainty factor of 10 for intrapopulation variability will be able to accommodate differences in sensitivity among various subpopulations, including children and the elderly. However, in cases where it can be demonstrated that a factor of 10 does not afford adequate protection, another uncertainty factor may be considered in conducting the risk assessment." (EPA 1998, at 65). As demonstrated by Martin et al. (2013), the use of a default uncertainty factor of 10 to account for intra-species variability is amply justified by empirical data on differences in human sensitivity related to genetic polymorphisms, gender, disease, old age, and toxicokinetics.

⁴⁵ The *Guidelines* note that (1) "Human studies covering a range of exposures are rarely available" and (2) "Evidence for a dose-response relationship is an important criterion in establishing a neurotoxic effect, although this analysis may be limited when based on standard studies using three dose groups or fewer." (EPA 1998, at 50 & 106).

As with the LOAEL analyses discussed above, application of the BMD methodology to the Xiang dataset produces an RfD for fluoride that is incompatible with water fluoridation. Specifically, applying EPA's BMDS software to Xiang's dataset produces a BMD of just **1.4 mg F/day**, if the BenchMark Response (BMR) is set at 5 IQ points, as displayed in the following figure.⁴⁶ This result can be interpreted as predicting that children exposed to 1.4 mg fluoride per day will have, on average, 5 less IQ points than children exposed to no fluoride. The RfD would obviously need to be set at a lower level, since such a large loss in IQ is clearly an adverse effect, and because uncertainty factors would need to be added to account for variation in sensitivity within a population as large as the U.S.

FIGURE 9: BMD for Loss of 5 IQ Points from Fluoride
(Linear Model, BMR = 5 IQ Points)

X. THE BROADBENT STUDY DOES NOT ESTABLISH THE SAFETY OF FLUORIDATION

Some commentators have incorrectly claimed that the recent study by Broadbent et al. establishes the safety of water fluoridation for neurologic development. The Broadbent study found no difference in the IQs of children and adults who spent their first 3 to 5 years of life in fluoridated (0.7 to 1.0 mg/L) vs. non-fluoridated (0 to 0.3 mg/L) areas of Dunedin, New Zealand. A glaring limitation with the Broadbent study, however, is that a substantial portion of the “non-fluoridated” control population used 0.5 mg/day fluoride tablets and fluoridated toothpaste, resulting in only a marginal difference in average total fluoride exposure between the fluoridated

⁴⁶ If the BMR is set at 1 IQ point, the BMD is 0.28 mg/day of fluoride.

and non-fluoridated populations.⁴⁷ In fact, in response to criticism on this point, (Osmunson et al. 2016), the authors conceded that the average difference in total daily intake between the children in the fluoridated and non-fluoridated areas would be ≤ 0.3 milligrams per day, while the average intake for all subjects was 0.9 mg/day.⁴⁸ (Broadbent et al. 2016). At most, therefore, the Broadbent study established that ≤ 0.3 milligrams of fluoride was not a sufficiently large enough contrast in daily fluoride exposure to produce a demonstrable effect on *average IQ* in the study cohort. This does *not* mean, however, that the fluoride exposures in a fluoridated community are safe, since no truly low exposure comparison group existed in the Broadbent study, and the Broadbent team made no attempt to study vulnerable subsets of the population (e.g., those with suboptimal nutrition, genetic polymorphisms, etc).

The inherent limitation resulting from the Broadbent study's comparison of populations with marginal contrasts in fluoride intake highlights an important strength of the endemic fluorosis/IQ studies from China, India, Iran, and Mexico. Specifically, the endemic fluorosis studies have generally compared communities with clear and stable contrasts in fluoride exposure, thus increasing the power of these studies to detect fluoride's effect on IQ. Moreover, unlike Broadbent's study, many of the endemic fluorosis studies have analyzed the relationship between IQ and individual measures of exposure (e.g., individual urine fluoride levels), thus overcoming the limitation imposed by Broadbent's ecological (group level) estimates of fluoride intake. Although Broadbent and others have criticized the endemic fluorosis studies for failing to control for potential confounders, several of these studies did carefully control for confounders and the association between fluoride and cognitive impairment remained intact. (Choi et al. 2015; Rocha Amador et al. 2009; Xiang et al. 2003a,b; Xiang et al. 2013). Further, while it's undisputed that many of the IQ studies used relatively simple study designs, the consistency of these studies, and their repeated corroboration by research showing that fluoride impairs learning in rodents under carefully controlled laboratory conditions, gives confidence to the conclusion that fluoride is a neurotoxin that impairs cognition.

For the foregoing reasons, the reference dose for protecting against fluoride neurotoxicity cannot reasonably be based on a risk assessment that treats the Broadbent study as establishing 0.7 to 1.0 mg/L as a NOAEL without application of an uncertainty factor(s) to account for intra-human variability and other issues left unanswered by Broadbent's study. Indeed, as spelled out in the *Guidelines*, it is problematic to develop an NOAEL based on a single study of a single neurotoxic endpoint,⁴⁹ particularly a study with such limited "dose spacing" between the groups.⁵⁰

⁴⁷ There are several other significant problems with the Broadbent study as well. First, the study did not collect any data on individual water intake or internal biomarkers of fluoride exposure (e.g., urine fluoride, etc). Second, the study used a crude estimate of fluoride toothpaste usage ("always" vs "sometimes" vs "never") that fails to account for the frequency of brushings per day and actual amount of toothpaste used per brushing, thus obscuring the very large variations of daily exposure that occur among children using fluoride toothpaste. Zohoori et al. 2012; Levy & Guha-Chowdhury 1999, tbl 3. Third, it did not control for potential confounders including blood lead and maternal IQ, even though such information was available and there are plausible reasons for the non-fluoridated subjects to have elevated lead exposure from living in a more rural area known for its highly corrosive drinking water. (Osmunson et al. 2016).

⁴⁸ A previous study of total fluoride intake among 3-to-4 year olds in fluoridated and non-fluoridated areas of New Zealand found the daily intakes to be 0.68 ± 0.27 and 0.49 ± 0.25 mg F/day, respectively. (Guha-Chowdhury et al. 1996).

⁴⁹ According to the *Guidelines*, "Neurotoxic effects (and most kinds of toxicity) can be observed at many different levels, so only a single endpoint needs to be found to demonstrate a hazard, but many endpoints need to be examined to demonstrate no effect. For example, to judge that a hazard for neurotoxicity could exist for a given agent, the minimum evidence sufficient would be data on a single adverse endpoint from a well-conducted study. In

XI. THE BENEFITS OF PREVENTING FLUORIDE NEUROTOXICITY DWARF THE COSTS OF RESTRICTING FLUORIDE CHEMICALS

EPA's authority to act under Section 6 of TSCA is premised on two distinct findings: (1) a *risk* exists and (2) the risk is *unreasonable*. Here, in evaluating the preliminary question of whether a neurotoxic risk exists from use of fluoridation chemicals, the EPA is duty bound to follow its *Guidelines*, as the Agency has stated it “will follow” the *Guidelines* when “evaluating data on *potential* neurotoxicity associated with exposure to environmental toxicants.” (EPA 1998, at 3). For the reasons set forth above, a good faith application of these *Guidelines* to the current research on fluoride will show that neurotoxicity is a hazard of fluoride exposure, and that the doses associated with this hazard overlap the doses—as reflected by (a) total daily intake, (b) urinary fluoride level, (c) serum fluoride level, and (d) severity of dental fluorosis—that U.S. children are exposed to in areas with fluoridated water. Neurotoxicity must thus be considered a risk from adding fluoridation chemicals to drinking water.

Petitioners now turn, therefore, to the second prong of the inquiry: whether the neurotoxic risk posed by fluoridation chemicals is an unreasonable one. As EPA has stated, the reasonableness inquiry considers the benefits of reducing the risk with the costs of doing so. EPA (1985); 15 U.S.C. § 2605(c)(A). In considering these respective benefits and costs of risk reduction, EPA has stated it will take into account “the extent and magnitude of risk posed; the societal consequences of removing or restricting use of products; availability and potential hazards of substitutes, and impacts on industry, employment, and international trade.” EPA (1985); see also 15 U.S.C. § 2605(c)(A). We turn now to a consideration of these factors

A. Extent and Magnitude of Neurotoxic Risk from Fluoridation Chemicals

There is little question that neurotoxicity is a serious insult to health. (Grandjean & Landrigan 2014). In a nation besieged by neurological disorders of poorly understood etiology, both in young children and the elderly, minimizing exposures to known neurotoxic substances should be a public health priority. (*Id.*)

The reduction in IQ associated with fluoride exposure has been found to be severe enough in some children to produce mental retardation. (*E.g.*, Lin et al. 1991). But even the loss of a single IQ point is associated with significant economic loss. As calculated by Spadaro et al. (2008), a loss of a single IQ point causes an average drop in lifetime earnings of \$18,000 in 2005 U.S. dollars, which, when adjusted for inflation, amounts to \$22,250 in current dollars.⁵¹ Since 200 million Americans now live in areas where water is fluoridated,⁵² and since virtually all Americans consume processed foods and beverages made with fluoridated water, any reduction in IQ from consumption of fluoride-treated water stands to have very large economic consequences.

contrast, to judge that an agent is unlikely to pose a hazard for neurotoxicity, the minimum evidence would include data from a host of endpoints that revealed no neurotoxic effects.” (EPA 1998, at 55).

⁵⁰ According to the *Guidelines*, “the NOAEL is also directly dependent on the dose spacing used in the study.” (EPA 1998, at 57)

⁵¹ We adjusted for inflation by using the U.S. Bureau of Labor Statistics’ CPI Inflation Calculator at <http://data.bls.gov/cgi-bin/cpicalc.pl>.

⁵² The CDC states that 211,393,167 Americans now drink fluoridated water; the vast majority of this population is consuming artificially fluoridated water, as CDC estimates that only 11,883,007 Americans have “naturally” fluoridated water. See: <http://www.cdc.gov/fluoridation/statistics/2014stats.htm>

While the precise extent to which fluoridation is reducing IQ in the U.S. cannot yet be calculated, the dose-response data from Wang et al. (2012) indicates that daily consumption of a liter of fluoridated water per day (=0.7 mg F/day) during childhood would cause IQ to drop by an average of 2.5 points when compared to children with no exposure to fluoride, while consumption of half a liter per day (=0.35 mg F/day) would cause IQ to drop by an average of 1.25 IQ points. (Wang's data is consistent with a linear, no threshold, dose-response relationship between fluoride and IQ, and we have applied Wang's data here with that assumption.)

In 2010, there were 74.2 million children under the age of 18 living in the U.S., of which we can estimate roughly 50 million were living in fluoridated areas.⁵³ US Census Bureau (2011). If we apply Wang's dose-response data and assume that these 50 million children consumed between 0.5 to 1 liters of fluoridated water per day during childhood, fluoridation would have caused a loss of between 62.5 to 125 million IQ points. Based on the earnings data from Spadaro et al. (2008), a loss in the range of 62.5 to 125 million IQ points represents a total loss in lifetime earnings of between \$13.9 to 27.8 *trillion* for this generation.

Due to the sheer number of people exposed to fluoridation chemicals, even if only sentinel or susceptible populations in fluoridated areas suffer IQ loss, the economic impacts will still be substantial. For example, even if we conservatively assume that only 1 to 5% of children in a fluoridated area suffer any IQ loss,⁵⁴ and even if this IQ loss averaged just 1 IQ point,⁵⁵ this would still amount to 500,000 to 2,500,000 lost IQ points, with a total loss in lifetime earnings ranging from \$11.1 billion to \$55.6 billion for this generation alone.

In short, because of the *massive* extent of exposure to fluoridation chemicals in the U.S., even small effects on IQ will have very substantial economic consequences.

B. Societal Consequences of Restricting Use of Fluoridation Chemicals

If EPA exercised its authority under TSCA to ban the waterborne use of fluoridation chemicals, the one and only potential societal consequence would be an increase in tooth decay. Current research, however, indicates that any increase in dental treatment costs would be small, inconsistent, and far less than the loss in earnings associated with even small drops in IQ.

First, Petitioners wish to call the Agency's attention to the fact that there are no randomized controlled trials on the effectiveness of fluoridation, and few of the available studies adequately account for potential confounders like socioeconomic status, sealants, and dietary habits. (Iheozor-Ejiofor et al. 2015; Cheng et al. 2007). The evidence has thus been characterized by the Cochrane Collaboration as having "high risk of bias" and limited applicability to modern lifestyles. (Iheozor-Ejiofor et al. 2015).

⁵³ According to the CDC, 66% of the U.S. population receives fluoridated tap water. See: <http://www.cdc.gov/fluoridation/statistics/fsgrowth.htm>.

⁵⁴ We base the 1 to 5% estimate on the approximate percentage of children with serum fluoride levels in the range (~0.05 mg/L) associated with a 4-point IQ drop (n = ~1%), and the approximate percentage of children with urinary fluoride levels (≥ 1.3 mg/L) associated with clear reductions in IQ (n = 5%). For discussion of this data, see pages 9 to 12 above. Since the serum and urinary fluoride data is for the *general population*, these estimates likely *understate* the percentage of children in *fluoridated* areas with serum and urinary fluoride levels in this range.

⁵⁵ This is a substantially lower loss in IQ than would be predicted by existing research. As noted in footnote 54 above, the serum fluoride level (~0.05 mg/L) upon which this estimate is based was associated with a 4-point drop in IQ by Xiang et al. (2011). Further, research on susceptible populations has found dramatic losses in IQ from fluoride exposure, including an average 15-point drop among malnourished children with mild fluorosis. Das & Mondal (2016).

Second, methodological limitations notwithstanding, modern studies of fluoridation and tooth decay have found that the difference in cavity rates between fluoridated and non-fluoridated areas is small, inconsistent, and often non-existent, particularly in the permanent teeth. (Chankanka et al. 2011a,b; Maupome et al. 2007; Warren et al. 2006; Shiboski et al. 2003; Colquhoun 1997; Heller et al. 1997; Diesendorf et al. 1997; Leroux et al. 1996; Brunelle & Carlos 1990; Yiamouyiannis 1990; Hildebolt et al. 1989).

Because of the small and inconsistent differences in cavities now seen between fluoridated and non-fluoridated areas, sensitive measurements of tooth decay must be utilized in order to detect *any* differences in decay.⁵⁶ But, even when sensitive measurements are utilized, the differences remain small in absolute terms, inconsistent, and overshadowed by the influence of other factors known to affect decay. (Chankanka et al. 2011a; Warren et al. 2006; Armfield & Spencer 2004). A large-scale study in Australia, for example, found that adolescents who consumed fluoridated water their entire life had just 0.08 less decayed tooth surfaces (1.35 vs. 1.43 DMFS) than adolescents who consumed non-fluoridated water their entire life. (Armfield & Spencer 2004, at 290 tbl.3). Consistent with these findings, studies from Canada, Cuba, Finland, Germany, and the United States did not detect *any* measurable increase in decay following the termination of water fluoridation programs.⁵⁷ (Maupome et al. 2001; Burt et al. 2000; Kunzel et al. 2000a,b; Seppa et al. 2000).

Third, one of the few *empirical* investigations of *actual* dental costs in fluoridated vs. non-fluoridated areas found little meaningful difference in frequency or costs of treatment. (Maupome et al. 2007). The study examined the frequency and costs (in 1995 U.S. dollars) of restorative dental procedures over a six-year time period in fluoridated and non-fluoridated areas of Oregon and Washington. Consistent with other recent research, the authors noted that the difference in frequency and costs of dental treatment was “generally small,” with several of the age groups in the fluoridated areas having a higher frequency of dental treatment procedures than their peers in the non-fluoridated areas. (Maupome et al. 2007, at 228, tbl. 3). In total, the dental treatment costs in the fluoridated areas over the six-year period averaged \$355 versus \$387 in the non-fluoridated areas.⁵⁸ (*Id.* at 228, tbl. 4). When adjusted to 2016 dollars, the average difference in dental costs was thus only \$51 over the 6-year period, *or just over \$8 per person per year*. With an average life expectancy of 78.8 years,⁵⁹ the Maupome study suggests that fluoridation saves an average of \$665 in lifetime dental costs in the U.S. This amounts to less than 3 percent of the reduction in lifetime earnings that results from the loss of a single IQ point (\$22,250).

Finally, the cost-effectiveness study (Griffin et al. 2001) that advocates of fluoridation generally rely upon, is based on theoretical estimates that have several major, demonstrable problems that inflate the purported savings. (Ko & Thiessen 2015). The Griffin paper provides estimates of the annual savings in dental costs from fluoridation (in 1995 U.S. dollars) based on a review of several studies of caries rates in fluoridated vs. non-fluoridated communities. The paper estimates that fluoridation provides a net savings of anywhere from \$0.85 to \$33.71 per year.

⁵⁶ As evident by the studies of Yiamouyiannis (1990) and Brunelle and Carlos (1990), the difference in tooth decay between fluoridated and non-fluoridated populations, while detectable when calculated in terms of Decayed, Missing & Filled Surfaces (DMFS), is not large enough to be detectable when calculated in terms of Decayed, Missing and Filled Teeth (DMFT).

⁵⁷ A recent Canadian study by McLaren et al. (2016) reported an increase in decay following cessation of fluoridation in Calgary. However, as explained by Connett (2016), the entirety of this purported increase disappears when survey data omitted from the paper is considered.

⁵⁸ The average costs estimate is for people who had at least one restorative procedure during this time.

⁵⁹ See: <http://www.cdc.gov/nchs/fastats/life-expectancy.htm>

(Griffin et al. 2001, at 82, tbl. 4). Over the course of the average lifespan, this amounts to a lifetime savings ranging from \$67 to \$2656 per person when expressed in 1995 U.S. dollars. Adjusting for inflation, this amounts to a lifetime savings of \$106 to \$4,207 in 2016 dollars, which, even at its zenith, amounts to less than 20% of the costs (\$22,500) incurred from loss of a single IQ point

As discussed by Ko and Thiessen (2015), Griffin's cost-savings estimates suffer from several important limitations. First, and foremost, Griffin did not make any attempt to include the costs of treating dental fluorosis in the costs side of the ledger, thereby inflating the net savings. This is a particularly significant omission since Griffin elsewhere estimated, in a separate paper, that fluoridating water causes 2 percent of children to develop aesthetically objectionable fluorosis on their front teeth. (Griffin et al. 2002). With approximately 50 million children now living in fluoridated areas, this amounts to roughly 1 million children developing aesthetically objectionable fluorosis on their front teeth as a direct result of water fluoridation. But even this is an under-estimate, since Griffin based this on the NIDR's 1986-87 national survey, and more recent national surveys show that both the rate and severity of dental fluorosis have increased considerably over the past 20 years. (NHANES 2014; Beltran 2010). In fact, as mentioned earlier, the 2011-2012 NHANES survey found that an astonishing 21% of adolescents now have *moderate* fluorosis, and an additional 2% have severe fluorosis. (NHANES 2014) Since many children who have fluorosis staining on their front teeth will have it cosmetically treated,⁶⁰ the aggregate costs of this treatment will be substantial, and any cost-effectiveness evaluations of fluoridation that fail to account for these treatment costs will artificially inflate the cost-savings of fluoridation. Griffin's cost-savings estimates should not, therefore, be taken at face value, but even if they are, they suggest a range of lifetime savings for the current population under 18 (i.e., \$5.3 to \$210 billion) that is still substantially less than the range of earnings losses associated with fluoridation-related drops in IQ (i.e., \$11.1 billion to \$27.8 trillion).

C. Availability and Potential Hazards of Substitutes to Fluoridation Chemicals

The addition of fluoridation chemicals to drinking water began in the U.S. prior to the advent of topical fluoride products in an era when public health authorities believed fluoride's predominant benefit to teeth comes from *ingestion*. Things have changed dramatically since that time.

Today, over 95% of toothpastes contain fluoride, as do many other dental products, (CDC 2013c), and dental researchers now universally acknowledge that fluoride's predominant benefit is topical, not systemic. (E.g., Fejerskov 2004; Featherstone 2000). As explained in the *Journal of the American Dental Association*, "fluoride incorporated during tooth development is insufficient to play a significant role in cavity protection." (Featherstone 2000, at 891). The Centers for Disease Control has confirmed the primacy of fluoride's topical mechanisms, declaring that "fluoride's predominant effect is *posteruptive* and *topical*." (CDC 2001, at 4). The NRC has confirmed this as well, stating that "the major anticaries benefit of fluoride is *topical* and *not systemic*." (NRC 2006, at 13).

Since fluoride's primary benefit comes from topical contact with the teeth, there is little benefit from swallowing fluoride, in water or any other product. In fact, a recent study of the relationship between tooth decay and total daily fluoride ingestion failed to find a detectable relationship

⁶⁰ Research has found that teeth with dental fluorosis, including in its "mild" forms, is perceived as an objectionable condition that warrants dental treatment. (E.g., Alkhatib et al. 2004; Riordan 1993). Consistent with this, studies have repeatedly found that staining of the front teeth, including the white splotches of fluorosis, can cause children significant anxiety and distress about the appearance of their teeth. (E.g., Tellez et al. 2012; Marshman et al. 2008).

between the two. (Levy et al. 2009). Other recent studies investigating the relationship between tooth decay and individual biomarkers of fluoride intake (e.g., toenail fluoride content and dental fluorosis) have reported similar results. (Charone et al. 2012; Komarek et al. 2005).

The widespread availability of topical fluoride products highlights the lack of necessity of adding fluoridation chemicals to water, particularly since the quality of evidence for fluoride toothpastes has been recognized as vastly superior to the quality of evidence for water fluoridation.⁶¹ (Cheng et al. 2007, at 701). Furthermore, it is well established that western countries that do not fluoridate their water have tooth decay rates that are just as low, and often lower, as western countries that do fluoridate their water.⁶² (Cheng et al. 2007; Pizzo et al. 2007; Neurath 2005; Colquhoun 1997; Diesendorf et al. 1997; Bratthall et al. 1996; Diesendorf 1986).

While fluoride toothpastes and other fluoridated dental products carry their own potential hazards *when ingested*, these products—unlike drinking water—are not *designed* to be ingested. Further, unlike the addition of fluoridation chemicals to drinking water, the use of topical fluoride products does not result in the contamination of processed foods and beverages, thus making it easier to regulate the amount of fluoride ingested when topical fluoride products are the vehicle for delivering fluoride to those who want it.

D. Impacts on Industry, Employment & International Trade from Restricting Fluoridation Chemicals

Prohibiting the addition of fluoridation chemicals to drinking water will have little, if any, impact on industry, employment and international trade. The chemicals used for fluoridation are waste by-products of the U.S. phosphate industry and various Chinese fertilizer and chemical companies. The sale of fluoridation chemicals represents a very small portion of the U.S. phosphate industry's overall sales, and thus removing this very limited market will have little impact on the profitability of the phosphate industry. Finally, while ending fluoridation will curb *imports* of fluoridation chemicals from China, it will not impact American exports, because—to the best of Petitioners' knowledge—U.S. companies do not export fluoridation chemicals abroad. Accordingly, ending fluoridation will not have any disadvantageous impact on America's balance of trade.

XII. IT IS IN THE PUBLIC INTEREST FOR EPA TO ACT UNDER TSCA

EPA has recognized that TSCA invests the Agency with the authority to regulate drinking water additives. (EPA/FDA 1979). Although EPA also has certain authorities to regulate fluoride in drinking water under the SDWA, it is in the public interest for EPA to act under TSCA because it allows EPA to enact a far less expensive regulation that targets fluoridation chemicals in a more narrowly crafted manner that is justified on both policy and scientific grounds.

Under SDWA, the EPA can limit the legally permissible levels of chemicals in public drinking water supplies by enacting "Maximum Contaminant Levels" (MCLs). The EPA can effectively ban fluoridation under SDWA, therefore, by enacting an MCL below the so-called "optimal"

⁶¹ This is evident when comparing the Cochrane Collaboration's systematic review of the effectiveness of fluoride toothpastes with its systematic review of water fluoridation. *Compare* Iheozor-Ejiofor et al. (2015) *with* Marinho et al. (2003).

⁶² For additional data demonstrating the lack of difference in tooth decay rates between countries with extensive water (and/or salt) fluoridation and those without, Petitioners refer EPA to the documentation available at: <http://fluoridealert.org/studies/caries01/>

concentration of fluoride used in fluoridation programs (0.7 mg/L). Since an MCL does not distinguish, however, between fluoride that is *added* to water and fluoride that occurs naturally therein, implementing an MCL below the level used in fluoridation would force communities with elevated levels of naturally occurring fluoride to implement filtration programs. Banning fluoridation *indirectly* by reducing the MCL under SDWA would thus be more expansive in scope, and far more expensive in implementation, than a *direct* ban on fluoridation additives under TSCA.

As with other naturally occurring toxicants, like arsenic, Petitioners recognize that natural fluoride contamination of some rural water supplies is a problem that needs to be addressed. However, there is a distinct policy difference between a risk *imposed* on a population through the *purposeful addition* of a chemical to water, versus a risk that arises from a naturally occurring phenomena beyond human control. The difference between these two scenarios is material under TSCA because it speaks to the ease by which the risk can be eliminated, and thereby the *reasonableness* of continuing to endure the risk. Differential treatment of the two scenarios is thus justified.

Differential treatment is further justified by laboratory and epidemiological research linking artificial fluoridation chemicals (i.e., fluorosilicic acid and sodium fluorosilicate) with pipe corrosion and elevated blood lead levels. (Coplan et al. 2007; Maas et al. 2007; Macek et al. 2006; Masters et al. 2000). This research includes the CDC's own study of the issue, which analyzed the blood lead levels of children from the 1988-1994 National Health and Nutrition Examination Survey. (Macek et al. 2006).

Although the CDC study is sometimes touted as refuting the link between fluoridation and lead hazards, a close look at its data reveals that it is actually *consistent* with the fluorosilicate/lead thesis. As can be seen in Table 4 of the study, fluorosilicic acid was associated with:

- a 20% increased risk (but not statistically significant) for high blood lead levels among children living in houses made prior to 1946;
- a 40% increased risk (but not statistically significant) for high blood lead levels among children living in houses made between 1946 and 1973;
- a 70% increased risk (but not statistically significant) for high blood lead levels among children living in houses made after 1974;
- a 530% increased risk (which was statistically significant) for high blood lead levels among children living in houses with unknown ages.

Since three of these four elevated risks were not statistically significant, the CDC dismissed them as essentially random aberrations. However, the consistency in the *direction* of the risk, coupled with the large and significant five-fold increased risk for children in homes of unknown age, raises a serious red flag.

Even the CDC acknowledged that this study does not refute the connection between fluoridation and lead, and that "it is possible that larger samples might have identified additional, significant differences." (Macek et al. 2006, at 133). Indeed, when Coplan et al. re-analyzed CDC's data by placing all children exposed to fluorosilicic acid and sodium fluorosilicate in one group ("silicofluorides"), and all other children in another, they found that the children exposed to "silicofluoridated" water had a significantly elevated risk of having high blood lead levels. (Coplan et al. 2007, at 1039-40). According to Coplan's re-analysis, children from the silicofluoridated communities had a 20% greater risk of having blood lead levels in excess of 5

ug/dl. Coplan's team estimated that the risk for exceeding the 10 ug/dl threshold would be even greater. (*Id.* at 1039 tbl.9).

The repeated association between fluoridation chemicals and elevated blood levels provides further reason why it is in public interest for EPA to prioritize a targeted ban on fluoridation additives under TSCA over broad-based regulatory action against all fluoride in drinking water under SDWA.

XIII. CONCLUSION

Petitioners request that EPA exercise its authority under Section 6 of TSCA, 15 U.S.C. § 2605(a)(2), to prohibit the purposeful addition of fluoridation chemicals to U.S. water supplies. As set forth above, Petitioners make this request on the grounds that a large body of animal, cellular, and human research shows that fluoride is neurotoxic at doses within the range now seen in fluoridated communities. When considering the principles set forth in EPA's *Guidelines for Neurotoxicity Risk Assessment*, Petitioners submit that fluoridation is incompatible with a neurologically safe use of fluoride. Petitioners further make this request on the grounds that fluoride's predominant role in caries prevention comes from *topical* contact and thus there is no reasonable justification to expose hundreds of millions of Americans to the neurotoxic risks of *systemic* fluoride via water (and the many processed beverages and foods made therefrom) when topical fluoride products are now widely available for individual use. Most western nations, including the vast majority of western Europe, have already rejected water fluoridation. The EPA is the one federal agency with the authority to make this happen here in the U.S. We urge EPA to act accordingly.

Petitioners are represented by, and this Petition was prepared by:

X.	CONCLUSIONS.....	48

1 I, Philippe Grandjean, MD, DMSc, declare that:

2 1. I am a physician and environmental epidemiologist and serve as both an Adjunct Professor
3 at the Harvard T.H. Chan School of Public Health, and Professor and Chair of Environmental Medicine
4 at the University of Southern Denmark.

5 2. I was asked by Plaintiffs' counsel to provide an evaluation of the neurological health risks
6 associated with the exposure to fluoride in drinking water.

7
8 **I. SUMMARY OF QUALIFICATIONS**

9 3. A complete summary of my qualifications and publications can be found in my
10 Curriculum Vitae, which has been marked as Plaintiffs' Exhibit 3 and attached herein.

11 4. Over the past 25 years, my research has focused on developmental exposures to
12 environmental chemicals and the association with adverse health effects in children, as described in my
13 book "Only One Chance" (2013) published by Oxford University Press.

14 5. My research has been entirely funded by public sources, mainly the National Institutes of
15 Health (NIH). In 2003-2007, my study of children's vulnerability to environmental immunotoxicants
16 was supported by the U.S. Environmental Protection Agency (EPA). My current funding as principal
17 investigator includes grants from the Superfund Research Program at the National Institute of
18 Environmental Health Sciences and the U.S. Agency for Toxic Substances and Disease Registry
19 (ATSDR).

20 6. I have published about 500 scientific papers, of which most are research articles in
21 international scientific journals with peer review. My h-index in the Web of Science data base is 70, and
22 my work is cited in scientific journals well over a thousand times every year. Seven of my articles
23 published in the last 10 years have earned the attribute "Highly Cited Paper," i.e., they received enough
24 citations to place them in the top 1% of published papers in the field.

25 7. My study on the neurodevelopmental effects of prenatal mercury exposure in a birth cohort
26 from Faroe Islands was relied upon by the EPA as the critical study for the Agency's derivation of a
27

1 Reference Dose for methylmercury (EPA 2001).

2 8. I have served as a technical advisor to the World Health Organization on environmental
3 health issues, including five occasions where I was elected Rapporteur. I have also served on, sometimes
4 chaired, or acted as rapporteur for, expert committees under the auspices of the EPA, ATSDR, Food &
5 Drug Administration (FDA); NIH; White House Office of Science and Technology Policy; International
6 Agency for Research on Cancer (IARC), European Commission, European Environmental Agency,
7 European Food Safety Authority, and other organizations. I have also served for over 30 years as
8 Consultant in Toxicology for the Danish Ministry of Health.

9 9. I am (Founding) Editor-in-Chief of the journal *Environmental Health* (since 2002), which
10 ranks among the most frequently cited journals in the field. I also serve or have served on editorial
11 boards of about a dozen journals within medicine, environmental science, and toxicology. As editor and
12 as reviewer for other major journals, I frequently evaluate manuscripts on environmental epidemiology
13 and toxicology.

14 10. I have received various awards and honors for my scientific work, including the John R.
15 Goldsmith Award from the International Society for Environmental Epidemiology, which is given to
16 investigators for “sustained and outstanding contributions to the knowledge and practice of
17 environmental epidemiology.”

18 11. I have been retained as an expert on the impact of environmental chemicals on human
19 health by government bodies, including the U.S. Department of Justice (on behalf of the EPA) and the
20 State of Minnesota.

21 12. I first began studying fluoride in 1980 at the suggestion of Dr. Irving J. Selikoff, who was
22 my mentor at the Mt. Sinai School of Medicine during my two-year Senior Fulbright Scholarship. Upon
23 returning to Denmark, I initiated a series of studies on a cohort of workers who had been occupationally
24 exposed to fluoride. I have remained involved in fluoride research since that time and have published 16
25 peer-reviewed reports on fluoride exposure and toxicity in humans.

26 13. In 1984, I drafted the Environmental Criteria Document on fluoride for the World Health
27

1 Organization (WHO). Ten years later, I drafted the Criteria Document for an occupational exposure
2 limit value for fluorine for the European Commission. In 2006, I served as a reviewer of the National
3 Research Council's report *Fluoride in Drinking Water: A Scientific Review of EPA's Standards*.

4 14. During the past 10 years, my research work on fluoride has focused on its developmental
5 effects on the brain. In 2012, I published a meta-analysis of the epidemiological studies on fluoride and
6 IQ (Choi et al. 2012); in 2015, I published an epidemiological study of fluoride and IQ in China (Choi et
7 al. 2015); and, in December of 2019, I published an updated review of fluoride neurotoxicity, which
8 relied in part on the work that I have performed in this case (Grandjean 2019).

9 15. In addition to my work on fluoride, I also have expertise in Benchmark Dose (BMD)
10 analysis. My experience doing BMD analysis started about 20 years ago in connection with my research
11 on the neurodevelopmental effects of methylmercury in the Faroe Islands that was selected as the critical
12 study for risk assessment by the EPA. Based on this research, the EPA provided me with a contract to
13 produce a BMD analysis of the data, which I carried out in collaboration with my biostatistician
14 colleagues, Dr. Esben Budtz-Jorgensen and Professor Niels Keiding. The EPA relied on this BMD
15 analysis to establish the safe level for methylmercury exposure in the U.S. (U.S. EPA 2001).

16 16. In 2009, I served on an expert panel that assisted the European Food Safety Authority
17 (EFSA) in developing a guidance document on BMD analysis titled "Use of the Benchmark Dose
18 (BMD) Approach in Risk Assessment."

19 17. In 2013, Dr. Budtz-Jorgensen and I extended our BMD methodology in collaboration with
20 the International Pooled Lead Study Investigators, which was peer-reviewed and published in the journal
21 *Risk Analysis* (Budtz-Jorgensen et al. 2013). As part of this analysis, we developed a BMD for lead and
22 IQ by analyzing pooled data from multiple different cohort studies. The paper was co-authored by
23 leading scholars on lead neurotoxicity, including Drs. David Bellinger and Bruce Lanphear.

24 18. More recently, Dr. Budtz-Jorgensen and I conducted an advanced BMD analysis on
25 perfluorinated chemicals, which was published in 2018 in the peer-reviewed journal *PLOS One* (Budtz-
26 Jorgensen and Grandjean 2018). In total, our achievements on BMD approaches and applications have
27

1 been published in seven articles so far in international biostatistical and biomedical journals.

2 19. In addition to my scientific training, I remain mindful, of the importance of translating the
3 results of epidemiological studies in a way that can facilitate public participation in making informed
4 decisions to protect their health, even prior to a “final proof” of causation being available; a final proof
5 that, all too often, has come too late to protect the public from harm, as reviewed most recently in the
6 monograph on *Late Lessons of Early Warnings*, published by the European Environment Agency (EEA
7 Report No 1/2013), for which I served as an editor. As Dr. Selikoff once impressed upon me, “Never
8 forget that the numbers in your tables are human destinies, although the tears have been wiped away.”

9 **II. SUMMARY OF OPINIONS**

10 20. The weight of epidemiological evidence leaves no reasonable doubt that developmental
11 neurotoxicity is a serious human health risk associated with elevated fluoride exposure, including those
12 occurring at the levels added to drinking water in fluoridated areas. The IQ losses associated with
13 community water fluoridation are substantial and of significant public health concern.

14 21. Application of the Benchmark Dose (BMD) methodology to the recent prospective birth
15 cohort data shows that the level of fluoride added to water in fluoridation programs greatly exceeds the
16 science-based limit needed to protect against developmental neurotoxicity.

17 22. The systematic review conducted by Dr. Ellen Chang, when corrected for its biases and
18 errors in judgment, further supports my opinions on the neurotoxic risks posed by elevated fluoride
19 exposure.

20 **III. SUMMARY OF METHODOLOGY**

21 **A. Weight of the Evidence**

22 23. I conducted a weight of the evidence assessment of available research on fluoride
23 neurotoxicity, with an emphasis on the epidemiology. While I place the greatest weight on the strong
24 epidemiological evidence, I also consider toxicokinetics, experimental toxicology data, and background
25
26
27

principles of brain development as part of my comprehensive analysis.

24. My review focuses on the evidence that carries the greatest weight which, as generally accepted, emphasizes the recent prospective cohort studies.

25. My methodology follows the general approach applied by the EPA, in the sense that I did a weight of the evidence analysis that focuses on the best available science (e.g., EPA 2017).

26. In light of my familiarity with the scientific literature on fluoride neurotoxicity, I did not conduct a formal systematic review on this occasion. Instead, my conclusions rely on a comprehensive and thorough review supplemented by a Benchmark Dose analysis of the recent prospective data.

27. I have read and considered the systematic review conducted by Dr. Ellen Chang, which mostly relies on the same evidence and which further confirms and supports my assessment of the literature. My opinions are thus fully informed by the insights offered by a formal systematic search of the literature.

B. Factors Considered When Assessing Epidemiological Literature

28. In evaluating the weight of the evidence, the question must be asked what each study could potentially reveal, given the design and choice of study parameters, including such factors as the precision of the exposure assessment. In the field of epidemiology, there is a well-known bias toward the null, e.g., from imprecise assessment of the exposure, of which epidemiologists (and readers of epidemiology reports) need to be careful, especially when human health is at stake (EPA 2005).

29. The following Table highlights common causes of bias toward the null in epidemiological studies, i.e., reasons that a study might not show the existence of a risk that indeed is present, though hidden due to the bias. While biases in the opposite direction also exist, they are usually of much less significance (Grandjean 2013).

*Table 1. Causes of bias toward the null in epidemiology studies
(Grandjean 2013a).*

Inadequate statistical power in small studies
Lost cases and inadequate follow-up for long-term effects
Exposed or otherwise inappropriate comparison (control) group
Exposure misclassification
Insensitive or imprecise outcome measures
Failure to adjust for confounders with effects in the opposite direction
Disregarding vulnerable subgroups
5% probability level to minimize risk of false positives (Type I error)
20% probability level to minimize risk of false negatives (Type II error)
Pressure to avoid false alarm

30. Studies that do not show a statistical significance are sometimes called “negative,” although this term is misleading. Joint analyses of several such studies may well show a significant difference or trend.

31. Observational studies will rarely if ever provide definitive proof of causation, and it is always possible for someone to raise doubts and uncertainties that require additional or improved data to resolve (Michaels 2008). It is important to recognize, however, that the presence of uncertainties often tends to cause underestimations of actual risks, not the opposite. This issue is of importance especially regarding substances that have not yet been studied in the detail desired or cannot be examined in randomized clinical trials. Many unfortunate past errors in regard to industrial chemicals have shown that initial assessments were often erroneous and led to an underestimation of the true risks (European Environment Agency 2001 & 2013).

32. In the context of developmental neurotoxicity, I place greatest weight on prospective studies of population-based birth cohorts followed over time (Grandjean et al. 2008; Grandjean & Landrigan 2014). Birth cohorts are crucial because it is not just the dose that can matter but also the timing of the dosing in regard to the developmental stage of the subjects (Grandjean et al. 2008; Grandjean et al. 2019). Follow-up studies of birth cohorts can thus reveal with greater certainty the

impacts of exposures incurred during early life stages.

C. Benchmark Dose Methodology

33. As part of my assessment in this case, I worked with my biostatistician colleague Dr. Budtz-Jørgensen on a BMD analysis of the prospective cohort data on fluoride and IQ using the same peer-reviewed method that we used for lead (Budtz-Jorgensen et al. 2013).

34. The statistical uncertainty in the BMD estimation is taken into account by calculating its lower one-sided 95% confidence limit, which is called the benchmark dose level (BMDL). The BMDL is then used as the point of departure for calculation of the exposure limit, by dividing the BMDL by an uncertainty factor (usually fixed at 10) to obtain a protective Reference Dose (RfD) or tolerable exposure (EFSA 2009; EPA 2012).

D. Materials Relied Upon

35. In my assessment, I relied upon my existing knowledge of the scientific literature (with citations to specific studies noted in my reports), my own meta-analysis of the epidemiological studies of fluoride and IQ (Choi et al. 2012), the more recent meta-analysis by Duan (2018), all available prospective studies, as well as the reviews by NRC (2006) and NTP (2016).

36. I also considered studies provided by counsel,¹ many of which I was already familiar with, and conducted supplemental searches on PubMed, including searches to see if there were any significant epidemiological studies published that I might have overlooked.

37. A complete list of the studies I relied upon is provided in my expert reports.

IV. GENERAL CONSIDERATIONS

A. Emergence of Brain Development as Vulnerable Target

38. Evidence has been accumulating over several decades that industrial chemicals can cause

¹ I understand that these studies were provided to EPA's experts as well, including Dr. Chang.

1 neurodevelopmental disorders that include learning disabilities, sensory deficits, developmental delays,
2 and cerebral palsy (NRC 2000), and current evidence also relates to other neurodevelopmental deficits,
3 such as attention deficit hyperactivity disorder (ADHD) (Bennett et al. 2016). Subclinical stages of these
4 conditions also appear to be common, and the suspicion of a link between neurotoxic chemical
5 exposures and widespread neurobehavioral damage has increased since it was first raised by research
6 demonstrating that lead is particularly toxic to the developing brain across a wide range of exposures
7 (Baghurst et al. 1987; Dietrich et al. 1987; Landrigan et al. 1975; Needleman et al. 1979).

8
9 39. The developing human brain is inherently much more susceptible to injury caused by toxic
10 agents than the brain of an adult. This susceptibility reflects the fact that in the nine months of prenatal
11 life the human brain must evolve from a strip of cells along the dorsal ectoderm into a complex organ
12 comprised of billions of precisely located, highly interconnected and specialized cells. Optimal brain
13 development requires that neurons move along precise pathways from their points of origin to their
14 assigned locations, that they establish connections with other cells near and distant, and that they
15 generate intercommunications in meaningful ways (Dobbing 1968; Rice and Barone 2000; Rodier
16 1995).

17
18 40. All of these processes must take place within a tightly controlled time frame, in which each
19 developmental stage must be reached on schedule and in the correct sequence. Due to the extraordinary
20 complexity of human brain development, windows of unique susceptibility to toxic interference occur
21 that have no counterpart in the mature brain, or in any other organ. Because of the unique structure of
22 the human brain and its advanced function, no other species shows similar degree of developmental
23 vulnerability. Thus, if a developmental process in the brain is halted or inhibited, there is little potential
24 for later repair, although plasticity will allow some compensation, and the consequences are therefore
25 likely to be permanent (Dobbing 1968; Rice and Barone 2000).

1 41. To test chemicals for developmental neurotoxicity, standardized protocols have been
2 developed using rodent models (OECD 2007). However, they may not necessarily be sufficiently
3 sensitive, as rodent brains are far less complex than human brains, and intrauterine brain development is
4 completed at a stage where the human fetal brain is still rapidly developing *in utero* for several more
5 weeks with possible continued impact from maternal transfer of neurotoxicants (Bal-Price et al. 2018).

6 42. During fetal development, the placenta can offer some protection against unwanted
7 chemical exposures, but it is not an effective barrier against most environmental neurotoxicants
8 (Andersen et al. 2000), including fluoride (NRC 2006). In addition, the blood-brain barrier, which
9 protects the adult brain from many toxic agents, is not completely formed until about 6 months after
10 birth (Adinolfi 1985).

12 43. Postnatally, the human brain continues to develop, and the period of heightened
13 vulnerability therefore extends over many months through infancy and into early childhood. While most
14 neurons have been formed by the time of birth, growth of glial cells and myelination of axons continue
15 for several years and is not complete until late teenage years (Rice and Barone 2000; Rodier 1995).

16 44. The susceptibility of infants and children to industrial chemicals is further amplified by
17 their relatively increased exposures in regard to body weight, their augmented absorption rates, and
18 diminished ability to detoxify many exogenous compounds as compared to adults (Ginsberg et al. 2004;
19 NRC 1993).

21 45. In 2005, when I evaluated the evidence of industrial chemicals regarding developmental
22 neurotoxicity, only five substances (arsenic, lead, methylmercury, polychlorinated biphenyls, and
23 toluene) fulfilled our criteria for causal relationship in humans (Grandjean and Landrigan 2006). Eight
24 years later, when we reassessed the evidence, we added six more substances, including fluoride
25 (Grandjean and Landrigan 2014), based on new evidence that had emerged.
26

1 46. Our 2014 assessment was focused on *hazard* (i.e., whether fluoride causes developmental
2 neurotoxicity in humans), not on *risk* (i.e., the exposure level at which this hazard may occur).
3 Substantial new evidence published since that time, particularly the prospective birth cohort studies,
4 now permit an assessment of risk.

5 **B. Toxicokinetics During the Fetal Period**

6 47. In my assessment, I considered the toxicokinetics of fluoride, with a particular focus on the
7 uptake, distribution and retention during the fetal period.

8 48. It is well accepted that fluoride crosses the placenta and reaches the fetus from the
9 mother's blood stream (NRC 2006; WHO 2006).

10 49. The first documentation of placental transfer in humans was the observation in 1974 (Shen
11 and Taves 1974) that fluoride concentrations in maternal and cord serum correlated well, with the cord
12 blood showing slightly lower concentrations. These findings were replicated in 1986 (Ron et al. 1986),
13 with results suggesting minor deviations depending on gestational age. A more recent study from an area
14 with water-fluoride levels of 0.4-0.8 mg/L showed that cord serum contained about 80% of the
15 concentrations occurring in maternal serum (Opydo-Szymaczek and Borysewicz-Lewicka 2007).
16 Consistent with this, French researchers measured fetal blood concentrations of fluoride after the
17 mothers were administered a small dose of sodium fluoride, and the elevations were statistically
18 significantly higher (2.6 $\mu\text{mol/l}$) than in a control group (less than 1 $\mu\text{mol/l}$) (Forestier et al. 1990).
19

20 50. A recent study from scientists at the University of California San Francisco (UCSF) further
21 confirms the placental transfer of fluoride (Uyghurturk et al. 2020). In this study, fluoride concentrations
22 were measured in the urine, blood, and amniotic fluid among pregnant women in fluoridated and non-
23 fluoridated areas of Northern California. Each additional 0.1 mg/L of fluoride in water was associated
24 with a significant increase in the fluoride levels in the amniotic fluid ($p < 0.001$), thus confirming the
25
26
27

transplacental passage of fluoride.

51. As would be expected, given the undeveloped nature of the blood-brain barrier during the fetal period, laboratory studies of animals exposed to prenatal fluoride have found significant elevations of fluoride in the brain (McPherson et al. 2018; Mullenix et al. 1995). Similarly, in aborted human fetuses, fluoride concentrations in the brain have been shown to be higher in geographic areas with endemic fluorosis as compared to controls at lower exposures (Du et al. 2008; He et al. 2008).

C. Toxicological Findings

52. Neurotoxicity is a documented hazard of fluoride exposure in laboratory animals (NRC 2006), which supports the plausibility of fluoride causing neurotoxic effects in humans.

53. One of the first U.S. reports on experimental fluoride neurotoxicity emerged when a new method was developed for computerized surveillance of rat behavior. Fluoride was selected for a test of the new methodology and showed clear neurotoxicity (Mullenix et al. 1995). The authors noted that the behavioral effects they observed in the rats are indicative of fluoride's potential ability to cause IQ deficits in humans. This assessment, which was made prior to the publication of any studies of fluoride and IQ in western journals, proved prescient.

54. Since the Mullenix study was published in 1995, many additional animal studies have documented neurochemical and anatomic changes in the brains of fluoride-treated animals. By 2006, the NRC concluded that there was enough neurochemical and anatomic data to conclude that fluoride interferes with brain functions by both direct and indirect means.

55. Among prominent adverse outcome pathways, the NRC concluded that fluoride is an endocrine disrupter that can affect thyroid function at intake levels as low as 0.01 to 0.03 mg/kg/day in individuals with iodine deficiency (NRC 2006).² Thyroid toxicity supports the plausibility of fluoride

² Large epidemiological studies published since the NRC report suggest that thyroid dysfunction is a relevant risk at elevated fluoride exposures in fluoridated communities, especially in

1 neurotoxicity because availability of thyroid hormone is crucial for optimal brain development (Rovet
2 2014).

3 56. At the time of the NRC's review, there was little data yet available on fluoride's impact on
4 behavior and cognition in animals, but considerable data has since been published. In 2016, the National
5 Toxicology Program (NTP) conducted a systematic review of these behavioral/cognitive studies (NTP
6 2016). Although NTP did not consider any of the neurochemical/anatomical effects, it still concluded
7 that the evidence is "suggestive of an effect on learning and memory" (NTP 2016, p. vii). The NTP
8 characterized its confidence in the evidence as "moderate" for adult studies, and "low" for the few
9 available developmental studies.
10

11 57. Additional animal research on learning/memory has been published subsequent to the NTP
12 review, and most of it has reported adverse effects. As is often the case, the animal studies on
13 learning/memory have limitations or discrepancies but given the general consistency in their findings
14 they continue to be *at least* "suggestive" of fluoride being a neurocognitive hazard.
15

16 **V. EPIDEMIOLOGICAL STUDIES (CROSS-SECTIONAL)**

17 **A. Neurotoxicity from Occupational Fluoride Exposure**

18 58. The neurotoxicity of chemicals is often first discovered from workplace exposures
19 (Grandjean and Landrigan 2006), which are later followed by case reports that involve children or
20 pregnant women from the general population (Grandjean 2013). The same is true of fluoride.
21

22 59. Although largely overlooked or ignored, Roholm first reported evidence of nervous system
23 effects in his seminal study of cryolite workers in Copenhagen (Roholm 1937): "The marked frequency
24 of nervous disorders after employment has ceased might indicate that cryolite has a particularly harmful
25 effect on the central nervous system" (p. 178). The nervous system effects reported by Roholm included
26 tiredness, sleepiness, indisposition, headaches, and giddiness (p. 138).

27 adults with iodine deficiency (Malin et al. 2018; Peckham et al. 2015).

60. My own mortality study of the cryolite workers studied by Roholm showed an excess of violent deaths (Grandjean et al. 1985), but information on the causes of death did not allow any conclusions on deaths from nervous system disease.

61. One of the challenges with occupational studies of fluoride-exposed workers is that the fluoride exposure usually occurs as part of a mixture. In the 1940s, scientists at the Manhattan Project recorded CNS effects in workers exposed to uranium hexafluoride gas (UF₆). They observed a “rather marked central nervous system effect with mental confusion, drowsiness and lassitude as the conspicuous features” and attributed it to the fluoride rather than uranium (Ferry 1944; Mullenix 2005).

62. Consistent with the observations of the Manhattan Project scientists, published case reports have highlighted difficulties with concentration and memory accompanied by general malaise and fatigue following occupational fluoride exposures (Spittle 1994).

63. More recently, skeletal fluorosis in workers was found to be associated with gradually progressive effects on the normal function and metabolism of the brain and other aspects of the nervous system (Duan et al. 1995), and application of neuropsychological tests (i.e., WHO’s Neurobehavioural Core Test Battery) have reported significant associations between workplace fluoride exposures and cognitive problems (Guo et al. 2008; Yazdi et al. 2011).

64. The available evidence from occupationally exposed workers supports the neurotoxicity of fluoride but does not allow any detailed consideration of its dependence on dose, timing, and duration.

B. Neurotoxicity in Endemic Fluorosis Areas

65. Fluoride toxicity has received particular attention in China, where widespread dental fluorosis indicates pervasive high exposures (Wang et al. 2012). Areas with high prevalences of dental (and skeletal) fluorosis are known as “endemic fluorosis” areas.

66. Although microbiologically safe, water supplies from wells, small springs or mountain

1 sources have created pockets of increased fluoride exposures near or within areas of low exposures, thus
2 representing optimal settings for epidemiological research because only the fluoride exposure would
3 likely differ between nearby neighborhoods. In addition, rural families in China move much less
4 frequently than U.S. families, thus facilitating assessment of impacts from long-term exposures. Chinese
5 researchers took advantage of this fact and published their findings, though mainly in Chinese journals,
6 and according to the standards of science at the time. The early research dates to the 1980s but has not
7 been widely cited, in part because of limited access to Chinese journals, in part because the notion of
8 adverse effects from fluoride intake has often been considered unwelcome.

9
10 67. Most of the studies on fluoride neurotoxicity from China, and other countries (i.e., India,
11 Iran, and Mexico), have focused on IQ measures as the endpoint of concern, with the clear majority of
12 these studies reporting inverse associations (i.e., higher levels of fluoride exposure are associated with
13 lower IQ).

14 68. Many of the studies from China have significant limitations, including lack of information
15 on covariates, missing information on study details, assessment of exposures on a community basis, and
16 use of cross-sectional study designs. The reports have also tended to be relatively brief and simple in
17 design. These deficiencies, which in some cases are rather severe, limit the conclusions that can be
18 drawn, but are unlikely to explain the almost uniformly consistent inverse associations that have been
19 reported.

20
21 69. While most of the endemic fluorosis studies have rather simple designs and may have
22 failed to control for confounding factors of possible importance, they also have important strengths,
23 including: 1) Stable populations with stable water-fluoride concentrations; many of the studies
24 specifically limited the populations to those who had lived in the community their entire life. 2) Unlike
25 in the U.S., children in rural China have very little exposure to fluoridated dental products (Zhu et al.
26
27

2003), thus making water a more important and reliable metric of fluoride exposure. 3) The studies in endemic fluorosis areas that have controlled for or excluded key confounding factors (arsenic exposure, iodine deficiency, parental education) were still capable of identifying clear associations between elevated fluoride exposure and cognitive deficits (Choi et al. 2012).

70. I will discuss the Chinese research on IQ in fluoride-exposed communities in more detail, but I begin first with studies that have examined other neurotoxicity endpoints, including neuropathological outcomes in aborted fetuses, neurobehavioral effects during infancy, and cognitive deficits and other neurological problems in adults.

1. Neurotoxic Endpoints in Fetuses and Neonates

71. In brain tissue obtained from aborted fetuses in endemic fluorosis areas, electron microscopy showed retarded cell growth in the cerebral cortex, with substantial cytology changes (He et al. 2008). A similar study used stereology to examine nerve cell numbers and volumes in fetal brain tissue and found lower densities (Du et al. 2008). A third study focused on neurotransmitters and receptors and found deviations that suggested neural dysplasia (Yu et al. 2008). Another study of aborted fetal brain tissue showed similar neurotransmitter results (Dong et al. 1993). These studies are consistent with prenatal fluoride exposure causing anatomic and biochemical changes in the fetal brain, as concluded by the NRC. A limiting factor, however, is that the elevated fluoride exposure in these studies came primarily from coal burning, which may have contributed other contaminants besides fluoride that were not assessed.

72. The impact of elevated fluoride in drinking water on neurological behavior in 91 neonates was assessed by Li et al. (2008). The study found that neonates born in an endemic fluorosis area (water-fluoride concentrations of 1.7 - 6.0 mg/L) scored more poorly on the standard Neonatal Behavioral Assessment, and that visual and auditory responses were also deficient, as compared to controls from

1 areas with less than 1 mg/L (Li et al. 2008). These findings are again consistent with the notion that
2 fluoride can affect the brain during the prenatal period, although neonatal neurological assessments can
3 be somewhat imprecise and may be only weakly predictive of subsequent brain development.

4 73. In a separate study, infants from an endemic area were examined at ages 3, 6, 9 and 12
5 months and scored significantly lower in mental and psychomotor development indices than those of the
6 control group (Chang et al. 2017). The exposed group also showed lower birth weight, and it is unclear
7 whether this difference can lead to confounding or if a lower birth weight is a concomitant effect of the
8 fluoride exposure. As with the fetal neuropathology studies, the source of fluoride exposure in this study
9 was coal, not water, which limits the conclusions that can be drawn due to the potential for confounding.
10

11 2. Neurotoxic Endpoints in Adults

12 74. Studies in China using cross-sectional designs have also found cognitive problems and
13 neurological symptoms in adults with skeletal fluorosis living in endemic fluorosis areas. Using
14 neuropsychological tests, including the Wechsler scale, 49 adult fluorosis patients (it is not clear whether
15 the patients were from a coal- or waterborne fluorosis area) were compared with controls and showed
16 deficits in language fluency, recognition, similarities, associative learning, and working memory (Shao
17 et al. 2003). Likewise, cognitive impairment in elderly subjects was clearly elevated in a waterborne
18 fluorosis area, although within-group assessment of urine-fluoride concentrations failed to show a clear
19 gradient of effect (Li et al. 2016). Excess occurrence of neurological symptoms has also been recorded
20 in both adults and children from waterborne fluorosis areas, with headaches being the primary
21 manifestation (Sharma et al. 2009).
22

23 3. Childhood IQ

24 75. As noted above, most of the epidemiological studies on fluoride neurotoxicity have
25 focused on IQ scores in childhood. In 2012, my colleagues and I published a meta-analysis of the
26
27
28

1 available 27 studies, most of which were published in China³ (Choi et al. 2012). Because these
2 published studies were conducted independently, we used meta-analysis—a quantitative, formal,
3 statistical technique—to systematically review and assess these published research studies to derive
4 conclusions about the neurotoxicity of fluoride. The outcome of the meta-analysis includes a more
5 precise estimate of the association than any individual study that contributes to the pooled analysis. The
6 variability or heterogeneity in study results was also examined. We did not attempt to generate any
7 dose-response relationship, and the fluoride concentrations were used only for definitions of high and
8 low (reference) groups in each study.
9

10 76. Among the 27 studies we reviewed, two involved populations exposed to fluoride from
11 coal burning (Guo et al. 1991; Li et al. 2010); the rest of the studies involved exposure to fluoride
12 through drinking water containing fluoride from soil minerals. The Combined Raven's Test – The Rural
13 Edition in China (CRT-RC) was used to measure the children's intelligence in 16 studies. Other
14 intelligence measures included the Wechsler Intelligence scale (3 studies), Binet IQ test (2 studies),
15 Raven's test (2 studies), Japan IQ test (2 studies), Chinese comparative intelligence test (1 study), and
16 the mental work capacity index (1 study). As each of the intelligence tests used is designed to measure
17 general intelligence, we used data from all eligible studies to estimate the possible effects of fluoride
18 exposure on the children's intelligence. We conducted a sensitivity analysis restricted to studies that
19 used similar tests to measure the outcome (specifically, the CRT-RC, Wechsler Intelligence test, Binet
20 IQ test, or Raven's test), and an analysis restricted to studies that used the CRT-RC. We also performed
21 an analysis that excluded studies with possible concerns about co-exposures, such as iodine status and
22 arsenic exposure, or with non-drinking water fluoride exposure from coal burning, without finding
23 appreciable differences, as described below.
24
25

26
27 ³ Two of the 27 studies included in the analysis were conducted in Iran (Poureslami et al.
28 2011; Seraj et al. 2006), otherwise the study cohorts were populations from China.

77. The levels of fluoride exposure in the studies we examined, while higher than those associated with fluoridation programs (0.7 mg/L), are not as high as some have claimed. A surprising number of commentators, including the EPA, have only mentioned the *highest* concentration examined in the studies (11.5 mg/L) (Allukian et al. 2018; EPA 2018), although this high concentration occurred in only one of the 27 studies. The majority of studies that reported the water-fluoride level in the exposed group had between 1.5 and 4 mg/L, which is elevated, but only modestly.⁴ Similarly, Duan's more recent meta-analysis of waterborne fluoride exposures reported that 18 of 27 studies addressed water-fluoride concentrations below 4 mg/L, and IQ reductions were observed at elevated concentrations of 1 to 2 mg/L (Duan et al. 2018 Table 2).

78. Among the 27 studies, all but one showed random-effect standardized mean difference (SMD) estimates that indicated an inverse association, ranging from -0.95 to -0.10 (one study showed a slight, non-significant effect in the opposite direction). The overall random-effects SMD estimate (and the 95% confidence interval, CI) were -0.45 (-0.56, -0.34). Given that the standard deviation (SD) for the IQ scale is 15, an SMD of -0.45 corresponds to a loss of **6.75 IQ points**.⁵ I shall return to this result later. Among the restricted sets of intelligence tests, the SMD for the model with only CRT-RC tests and drinking-water exposure was lower than that for all studies combined, but the difference was not significant, and heterogeneity remained at a similar magnitude in the restricted analyses.

79. Several studies (Hong et al. 2001; Lin et al. 1991; Wang et al. 2001; Wang et al. 2007; Xiang et al. 2003; Zhao et al. 1996) reported other risk factors, such as iodine status, and exposure to arsenic or lead, both neurotoxicants, and our sensitivity analyses showed similar associations between

⁴ The fluoride levels in the control groups in the studies often approximated the concentrations (~0.7 mg/L) used in fluoridation programs. Some ill-informed commentators have mistakenly interpreted this to mean that these control levels are thereby safe. This is false. The control groups are not being compared to *lower* or zero fluoride groups, and, as such, provide no information about the safety, or lack thereof, of the control values.

⁵ The effect size we found is consistent with the prior meta-analysis of Tang (2008), who reported a mean difference of 5.03 IQ points between the high- and low-fluoride areas.

1 high fluoride exposure and the outcomes even after exclusion of these studies. Although large tracts of
2 China have superficial fluoride-rich minerals, there is little, if any, likelihood of contamination by other
3 neurotoxicants that would be consistently associated with fluoride concentrations in drinking water and
4 thereby systemically confound the results. For example, follow-up testing documented lower levels of
5 blood-lead concentrations and waterborne arsenic in the high-fluoride community than the control
6 (Xiang et al. 2003; Xiang et al. 2003; Xiang et al. 2013). In some instances, therefore, potential co-
7 exposure to other neurotoxicants may cause reverse confounding (i.e., may attenuate the real
8 relationship between fluoride and IQ), as we have documented for methylmercury exposure from
9 seafood (Choi et al. 2008).

11 80. Additional IQ studies in endemic fluorosis areas have been published since our 2012
12 review. As with the previous studies, these newer studies continue to replicate the consistent inverse
13 association between fluoride exposure and IQ, although many—but not all—suffer from similar
14 limitations. Two of the studies reported linear relationships between urinary fluoride excretion and IQ
15 (one study also included plasma-fluoride) among children living in areas with mean water-fluoride
16 contents of 1.4 mg/L and 1.5-2.5 mg/L (Cui et al. 2018; Zhang and Cheng 2015).⁶ Another study
17 published since our meta-analysis is the one I conducted with colleagues in China, which I will now
18 discuss.

20 81. To ascertain the validity of the Chinese reports on fluoride neurotoxicity, we carried out a
21 pilot study in Sichuan using methods commonly applied in neurobehavioral epidemiology (Choi et al.
22 2015). The children examined had lived in their respective communities since conception. Although we
23 examined only 51 children, our results are consistent with elevated fluoride exposure being a cause of
24 cognitive deficits. Interestingly, negative associations were found for cognitive function tests regarding

26 ⁶ These results are consistent with the findings of Ding et al. (2011), who reported a dose-
27 response relationship between urine-fluoride concentrations (range = 0.24-2.84 mg/L) and reduced IQ in
a population without any severe dental fluorosis (Ding et al. 2011).

all three measures of fluoride exposure. One was the known water-fluoride concentration at the residence where the child was born and had grown up, another was the child's morning urine-fluoride after having ingested fluoride-free water the night before (neither measure reached formal statistical significance as a predictor of cognitive deficits). The strongest and statistically significant association was seen with the degree of dental fluorosis that served as a marker of early-life fluoride exposure. While the milder forms of dental fluorosis have been considered a cosmetic effect (Aoba and Fejerskov 2002; WHO 2006), our study suggested that fluorosis can serve as a useful marker of early fluoride exposure in studies of neurodevelopmental toxicity.⁷

C. Studies of Fluoride and ADHD in North America

82. Four epidemiological studies have investigated the relationship between fluoride and ADHD behaviors in North America, the most important of which is the prospective cohort study by Bashash (2018). Two of the other three studies examined ADHD-related outcomes in the Canadian Health Measures Survey (CHMS) (Barberio et al. 2017; Riddell et al. 2019).⁸

83. In 2017, Barberio et al. examined two cycles of the CHMS to investigate the relationship between randomly measured urine-fluoride levels (in 3-to-12-year-old children) and parental reports or self-reported learning disabilities. When the two cycles of the CHMS were combined (both including at least 1,100 subjects), unadjusted urine-fluoride was significantly correlated with an increased incidence of learning disabilities. However, this effect lost its statistical significance after controlling for urine dilution by creatinine and specific gravity. The authors concluded that there was no robust association

⁷ A prior study that was co-authored by my colleague David Bellinger failed to observe a relationship between dental fluorosis and behavior, as determined from parental questionnaires (Morgan et al. 1998). Due to several weaknesses, the conclusions were cautious and, in the authors' wording, "cannot lay this issue to rest." The relationship between dental fluorosis and neurobehavioral deficits is an issue that thus requires further study, including the possibility that the relationship is only apparent for fluorosis of certain teeth that share windows of susceptibility that overlap the windows of susceptibility for developmental neurotoxicity.

⁸ The third study (Malin and Till 2015) was an ecological study that found an association between ADHD and water fluoridation in the U.S. This association was not robust, however, as it lost its significance after adjustment for altitude, although this adjustment is questionable.

between fluoride exposure and reported learning disability among Canadian children at the ages studied.

84. A more sophisticated study using the same CHMS data has now been completed and shows a significant association between fluoridated water and ADHD diagnoses/symptoms (Riddell et al. 2019). The latter study controlled for more potential covariates than Barberio and focused on an older subset of children (6 to 17 years old). Riddell's focus on an older group of children is an improvement because 90% of children with ADHD are diagnosed after age 6 (Riddell et al. 2019). Riddell also focused specifically on ADHD symptoms and diagnoses, rather than the broader category of "learning disabilities." The Riddell team also analyzed fluoride in water as well as in urine and conducted regression analyses to test the association with specific ADHD parameters: i.e., ADHD diagnosis and the hyperactivity/inattention score on the Strengths and Difficulties Questionnaire (SDQ).

85. After adjustment for covariates, including lead exposure, Riddell and colleagues found that fluoridation of the home water supply significantly increased the risk of an ADHD diagnosis. An increase in water-fluoride by 1 mg/L was associated with a (statistically significant) 6-fold higher odds of an ADHD diagnosis in the 710 children known to rely on community water, although this association was not replicated using urine concentrations that may have been more variable. Similar tendencies were seen for the SDQ scores of hyperactivity/inattention, especially among the older youth (not covered by the Barberio study).

86. With its individual exposure data, more specific ADHD outcomes in adolescents, and large effect size, the Riddell study, along with Bashash et al. (2018) that I will discuss below, provide additional weight to the evidence of fluoride being a neurotoxicant at current levels of exposure in fluoridated areas.

VI. EPIDEMIOLOGICAL STUDIES (PROSPECTIVE)

A. Prospective Cohort Studies with Individual Assessment of Prenatal Exposure

1 87. The most reliable evidence of developmental neurotoxicity is obtained through prospective
2 studies that include real-time recording of information about exposure in early life followed by
3 subsequent clinical assessments of the child. (Grandjean & Landrigan 2014; Grandjean 2008). In our
4 meta-analysis we recommended that prospective studies be conducted to formally evaluate dose-
5 response relations based on individual-level measures over time, including more precise prenatal
6 measurements (Choi et al. 2012). Five such studies have now been conducted, and they have each found
7 significant adverse associations between prenatal fluoride exposure and neurodevelopmental harm
8 (Bashash 2017; Bashash 2018; Green 2019; Valdez-Jiminez 2017), with an additional study finding an
9 association between fluoride exposure during early infancy and IQ loss (Till 2020). The quality of these
10 studies, coupled with the consistency of their findings, also in regard to the cross-sectional studies, add
11 *substantial* weight to the evidence for developmental neurotoxicity from fluoride exposure.
12

13 88. I understand that Dr. Hu and Dr. Lanphear will be discussing the ELEMENT and MIREC
14 cohort studies in detail, so I will forego doing so here. As I explained in my initial expert report, these
15 are high-quality studies given their prospective birth cohort design, individual measurements of fluoride
16 exposure, and extensive control for potential confounders.
17

18 89. In addition to the ELEMENT and MIREC studies, a prospective birth cohort study has also
19 been published from a separate area of Mexico where there are elevated levels of fluoride in drinking
20 water (Valdez Jiminez 2017). In this study, maternal urine-fluoride (corrected for specific gravity) was
21 examined for its association with scores on the Bayley Scales among 65 children evaluated at age 3-15
22 months. The mothers in the study had average urine-fluoride concentrations at each of the three
23 trimesters of pregnancy of 1.9, 2.0, and 2.7 mg/L. These fluoride exposure indicators during the first and
24 second trimesters were associated with large and significant reductions in the Bayley Mental
25 Development Index (MDI) (cognitive) score after adjusting for covariates, including gestational age.
26
27

1 While this study is not as robust as the ELEMENT and MIREC studies due to the limited size, its
2 findings are consistent with and reinforce their findings, and add further weight to the neurotoxicity
3 assessment given its prospective cohort design.

4 **B. Prospective Cohort Studies without Prenatal Exposure Assessment**

5 90. Two additional prospective studies have been previously published on fluoride and
6 neurodevelopment (Shannon et al. 1986; Broadbent et al. 2015), both from New Zealand. They have
7 substantial limitations that make them much less informative than the North American studies, including
8 a failure to obtain individual measurements of fluoride exposure, and a failure to ascertain prenatal
9 fluoride exposure.
10

11 91. The first of the New Zealand studies was published in 1986 by Shannon. It found no
12 association between childhood behavior (as scored by mothers and teachers) and the duration of time the
13 child had lived in a fluoridated area during the first 7 years of life. The authors, however, made no
14 attempt to ascertain prenatal and early postnatal exposures. Postnatal exposures were measured by
15 simply tallying the number of years a child resided in a fluoridated area, with no distinctions made for
16 the *timing* of postnatal exposure. Under this exposure metric, a child who lived her first year of life in a
17 fluoridated area (a period of increased vulnerability) would be treated the same as a child who lived her
18 seventh year of life in a fluoridated area.
19

20 92. A second prospective study from New Zealand was based on a birth cohort established
21 from births in 1972-1973 (Broadbent et al. 2015). The 1,037 children were recruited at age 3 years, and
22 IQ tests were administered at ages 7, 9, 11 and 13 years, and again at age 38. Urine samples were again
23 not available for analysis, and the authors had no individual data on water intake. Instead, the authors
24 compared individuals who had lived for an undefined period of time in a fluoridated area during their
25 first five years of life, with individuals who had not lived in a fluoridated area during their first five
26 years of life.
27

years. No significant differences in IQ were noted using this exposure metric, and this finding was independent of potential confounding variables, including sex, socioeconomic status, breastfeeding, and birth weight.⁹

93. The Broadbent study also made no attempt to ascertain prenatal exposures, including maternal tea consumption, which is an important limitation given the high rate of tea consumption in New Zealand. Tea contains elevated levels of fluoride, and tea consumption can be a major source of fluoride intake among adults (Waugh 2017). During the time that the children in this study were born (1972-1973), New Zealanders consumed as much as 2.6 kg of tea per capita per year (corresponding to 3-4 teabags per day), as compared to the consumption of 0.5 kg in Canada in the approximate time the MIREC cohort was recruited (Grigg 2002). The failure of both New Zealand studies to consider maternal tea consumption may have introduced substantial imprecision into the exposure classification.

94. An additional concern is that the 10% of cohort subjects who had not lived in fluoridated areas very likely received fluoride supplements, which would eliminate much of the (postnatal) difference in exposure between the fluoridated and non-fluoridated areas. In a letter published subsequent to the study, the authors estimated that the average difference in exposure between children in fluoridated vs. non-fluoridated areas was only 0.3 mg/day (Broadbent et al. 2016).

95. Based on the absence of individual measurements of exposure; failure to control for the timing of exposure, including prenatal exposures; and the relatively small difference in postnatal exposures in the Broadbent study, the New Zealand studies provide virtually no information about the neurotoxic impact of early-life fluoride exposures. They carry little weight in my assessment.

VII. SYSTEMATIC REVIEW

96. Although I decided not to conduct a formal systematic review for my weight-of-the-

⁹ Despite the fact that lead exposure in this cohort was later reported to cause IQ deficits (Reuben et al. 2017), the authors of the fluoride study chose not to control for exposure to lead or other chemicals that can affect neurodevelopment.

evidence analysis, I had the opportunity to consider and analyze the review conducted by Dr. Ellen Chang of Exponent. As I described in my expert rebuttal report, Dr. Chang's systematic review provides no credible grounds for questioning my assessment of the literature; in fact, it further supports it.

A. Dr. Chang's Systematic Review Confirms that I Considered All Significant Data

97. Dr. Chang stated that her systematic review identified numerous studies that I did not address, with the apparent implication that these studies are somehow at odds with my opinion (p. 8). What Dr. Chang failed to reveal, however, is that the great majority of these studies reported significant associations between fluoride exposure and neurotoxic outcomes, further confirming my own assessment.

98. Of the 31 studies that Dr. Chang has identified and which I did not specifically address, 27 found associations of elevated fluoride exposure with adverse effects.¹⁰ These studies, which provide further *support* for my opinions, were not cited in my report because most are repetitions of the cross-sectional study design in endemic fluorosis areas that I have already discussed at length; some are only available in abstract form;¹¹ some are secondary analyses of primary studies that I already addressed;¹² and one was not available to me at the time of submitting my report (Till et al. 2020). As explained in my report, I do not consider it necessary to address and discuss each and every paper that reports on fluoride effects, especially when peer-reviewed systematic reviews are available, including our own (Choi et al. 2012). I consider it more informative to examine the various *types* of studies, including toxicokinetics (e.g., distribution of fluoride throughout the body, including transfer through the placenta and blood-brain barrier); toxicological findings from animals; and different endpoints relevant to

¹⁰ Aravind (2016); Asawa (2014), Calderon (2000), Das (2016), Khan (2015), Kundu (2015), Liu (2000); Lu (2019), Manju (2017), Mustafa (2018), Nagarajappa (2013); Qin (1990), Razdan (2017), Rocha-Amador (2007), Rocha-Amador (2008), Rocha-Amador (2009), Saxena (2012), Shivaprakash (2011), Singh (2013), Sudhir (2009), Thomas (2018), Till (2019), Trivedi (2007), Wang (2005), Xiang (2015), and Yu (2018).

¹¹ Calderon (2000); Thomas (2018).

¹² Xiang (2015); Wang (2012).

neurotoxicity (e.g., cognitive tests, thyroid function, histological assessments of fetal brain).

99. Conversely, many of the studies that I addressed in my report¹³ were not considered by Dr. Chang for unexplained or spurious reasons. Dr. Chang's review, for example, never addressed or considered fluoride's (i) passage through the placenta, (ii) uptake into fetal brain, and (iii) neurochemical and anatomical effects, and she spuriously dismisses the evidence of neurotoxicity in adults as irrelevant to developmental effects in humans (p. 31). In several important ways, therefore, Dr. Chang's review is not as systematic as my own.

100. Dr. Chang's systematic search of the literature identified four papers that reported no significant associations with neurodevelopmental effects and that I did not rely on, but upon inspection, they have no material effect on the conclusions that can be drawn, as I will now discuss.

101. One study highlighted by Dr. Chang is a publication by Spittle and colleagues (Spittle 1998) that Dr. Chang refers to repeatedly throughout her review. Although noted in a lengthy table at the end, Dr. Chang fails to acknowledge in the body of her review that this report is in the form of an abstract and relates to a previous (full) publication (Shannon et al. 1986) that I addressed in my report (and above). I did not cite the Spittle abstract in my report, just as I did not cite abstracts of studies reporting harm.¹⁴ It is standard practice for systematic reviews to omit abstracts, as practiced in systematic reviews conducted by the authoritative Cochrane group (Iheozor-Ejiofor et al. 2015). Dr. Chang provides no justification for including abstracts in her review, such as the one by Spittle (Spittle 1998). Dr. Chang's prominent references to the Spittle abstract is particularly surprising given that it does not describe *any* confounder adjustment,¹⁵ and uses an ecological metric for exposure (group water

¹³ *E.g.*, Dong (1993); Duan (1995); Ekstrand (1981); Li (2016); Spittle (1994); Guo (2001); Malin (2018); Opydo-Szymaczek (2005, 2007); Peckham (2015); Ron (1986); Salgarello (2016); Shao (2003); Shen & Taves (1974); Yazdi (2011); Yu (2008).

¹⁴ Calderon (2000); Thomas (2018).

¹⁵ On p. 132 of her Table, Dr. Chang "assume[s]" that the Spittle analysis controlled for the same confounders as the Shannon analysis. I understand that neither Dr. Chang, nor anyone else in her

1 F level) – features which Dr. Chang has used to dismiss many papers that support the neurotoxicity of
2 fluoride.

3 102. The other three “no-effect” studies that Dr. Chang cites and that I did not address are
4 similarly unavailing. Two are cross-sectional studies from China which fail to show statistically
5 significant associations between fluoride exposure and IQ,¹⁶ and one is an ecological analysis (Perrott
6 2018) of the Malin & Till (2015) study on ADHD which I addressed but placed little weight on. As I
7 explained in my report, there are many reasons why an ecological/cross-sectional study can fail to detect
8 an effect even when one is present. The failure of these three studies to find statistically significant
9 effects does nothing to contradict the robust literature that I rely upon, including the prospective birth
10 cohort studies that I placed the greatest weight on. Even Dr. Chang appears to recognize this, as she does
11 not include any of these three studies in her causal analysis, and correctly notes that the analysis by
12 Perrott (Perrott 2018) is a “relatively low quality” ecological study (p. 66).
13

14 103. In summary, despite asserting that my review failed to consider “numerous” papers, Dr.
15 Chang’s own review confirms that I addressed and considered the most relevant epidemiological studies
16 on cognitive outcomes. Dr. Chang’s literature search also confirms that the majority of studies that I did
17 not specifically address are consistent with and further support the association between fluoride and
18 cognitive impairment, in accordance with my conclusions.
19

20 **B. Dr. Chang’s Review Fails to Identify Any Systematic Biases that Explain Fluoride’s**
21 **Consistent Association with Neurodevelopmental Harm**

22 104. Dr. Chang’s systematic assessment of study quality provides a lengthy discussion of real or
23 perceived methodological limitations in the available studies. Importantly, however, Dr. Chang failed to
24 identify a likely explanation for how these limitations can explain the consistent adverse associations
25

26 office has contacted Dr. Spittle to confirm this statement (Personal email communication with Bruce
27 Spittle, August 13, 2019). According to Dr. Spittle, the abstract provided all important methodological
28 details.

¹⁶ He (2010); Kang (2011).

1 between fluoride and IQ across both cross-sectional and prospective studies. For example, Dr. Chang
2 referred to “high potential for selection bias” but did not consider how unlikely it is that dozens of
3 studies should all suffer from some particular exposure misclassification or selectivity that would all
4 cause bias *away* from the null, e.g., selection bias that would result in participation of intellectually
5 disabled children only in the high-fluoride group, or residual confounding resulting in bias only away
6 from the null in the many different study settings.

7
8 105. Dr. Chang claimed that “methodological uncertainties remain about the assessment of
9 fluoride exposure and neurodevelopmental outcomes; and the reported findings are plausibly explained
10 by confounding, bias, and chance” (p. 9). However, she did not provide any convincing evidence that
11 such issues could have resulted in erroneous conclusions, especially in the high-quality prospective
12 studies.

13
14 106. Throughout her analysis, Dr. Chang failed to grapple with the fact that random (i.e., non-
15 differential) error is unlikely to cause a bias away from the null, as is well-known in epidemiology, as I
16 have also discussed in past publications (Grandjean and Budtz-Jorgensen 2007, 2010). Dr. Chang thus
17 did not articulate a plausible basis for why the limitations she claimed to have identified can
18 *systematically* bias the results across the many study settings, including the North American birth
19 cohorts.

20
21 107. Dr. Chang described cross-sectional studies as if they are all equal and as if the exposure
22 parameter always represents a current and short-lasting exposure only. In so doing, Dr. Chang failed to
23 acknowledge in her causal analysis that exposure measures in many studies represent long-term
24 community conditions, in some studies also likely covering prenatal exposures, a critical detail.

25
26 108. Dr. Chang referred to exaggerated associations that can result from lack of blinding (p.
27 59), but failed to acknowledge that at least 11 of the studies reporting adverse neurocognitive effects

1 have clearly been blinded, including the recent birth cohort studies, where the exposure was determined
2 *after* the cognitive tests had been completed. Thus, while lack of blinding can create observation bias, it
3 cannot explain the inverse association between fluoride and IQ because similar associations have been
4 consistently found in studies known to be blinded. Despite producing a 56-page table to address “key
5 characteristics” of the studies, Dr. Chang failed to mention this methodological strength in her summary
6 of the studies (pp. 90-146).

7 109. Dr. Chang repeatedly highlighted the risk of publication bias, e.g., in the biomedical
8 journal *Fluoride*, which is not indexed by PubMed. However, she does not mention the bias *against*
9 publication, i.e., a bias that acts in the opposite direction. The examples that I mentioned in my report
10 illustrate that such bias exists.¹⁷ Further, Dr. Chang speculated that Chinese-language studies that did
11 not find adverse effects may not have been translated into English (p. 37). Instead of speculating about
12 this, Dr. Chang’s systematic review could have included a search of online databases of Chinese-
13 language research (e.g., CNKI) but, for unexplained reasons, did not do so.¹⁸

14 110. In summary, although Dr. Chang’s systematic assessment of study quality correctly
15 identified limitations in a number of studies, she failed to credibly explain how these limitations can
16 plausibly explain the significant inverse associations that have consistently been found across many
17 study settings and designs.¹⁹ Although I recognize the issues that Dr. Chang has raised and have fully
18

19
20
21 ¹⁷ The desire to use fluoride in caries prevention programs has sometimes made it difficult
22 for researchers, including myself, to present findings of potential toxic effects. In addition to my own
23 personal experiences, published case reports suggest that some studies reporting adverse results have
24 been suppressed, and, in at least one instance, a respected scientist at the Forsythe Dental Institute lost
25 her job after publishing evidence of neurotoxicity.

26 ¹⁸ A search of PubMed for “CNKI database” shows that many systematic reviews include
27 CNKI as one of the databases to retrieve studies, and the Institute of Medicine recommendations for
28 systematic review (which Chang relies on) calls for searching for foreign language studies when
appropriate (IOM 2011, p. 8). CNKI is publicly available online at:
<http://oversea.cnki.net/kns55/default.aspx>.

¹⁹ Unable to explain why so many studies have found significant associations between
fluoride and IQ, Dr. Chang claims that “most published scientific research findings are anticipated to be
false” (p. 38, citing Ioannidis (2005)). Although the original report by John Ioannidis (Ioannidis 2005)

considered them in my assessment, it remains extremely unlikely, if not impossible, that the overwhelming evidence of fluoride neurotoxicity is a mirage caused by bias, as Dr. Chang apparently believes. A far more likely and plausible explanation for the consistent findings in the epidemiological studies is that fluoride is a developmental neurotoxicant that reduces IQ and that this association is strong enough to be apparent also in studies with less-than-ideal designs.

C. Bradford Hill Aspects Support, Rather than Detract from, the Causal Nature of Fluoride's Association with Neurodevelopmental Harm

111. Dr. Chang used the Bradford Hill aspects to evaluate the causal relationship between fluoride and neurotoxicity. As I explained in my rebuttal report, her causal analysis is superficial and pays lip service only to Sir Austin's wise advice. An appropriate and systematic assessment of the Bradford Hill guidelines supports, rather than refutes, the causal relationship between elevated fluoride exposure and IQ loss. I will summarize here:

112. *Strength*: Dr. Chang dismissed the strength of the association between fluoride and IQ on the grounds that a loss of 3 to 5 IQ points is relatively small in comparison with normal, expected variation (p. 69). Under this arbitrarily high standard, other well-known neurotoxicants (e.g., lead, methylmercury, arsenic) would fail Dr. Chang's strength criterion. By failing to consider the strength of association of other well-known neurotoxicants, Dr. Chang subjectively analyzed the data on fluoride in a meaningless vacuum. Had Dr. Chang considered the strength of association for other neurotoxicants, she would have found that the effect size for fluoride actually is actually large, not small (i.e., it rivals the effects of lead), which *supports*, rather than detracts, from a causal relationship.

113. *Consistency*: One of the most compelling aspects about the epidemiological research on

did provide some stunning examples of how clinical medicine could be misled by single reports, it would be reckless and counterproductive if we were to ignore all published reports, as Dr. Chang seems to prefer. This nihilistic view was also not the intent of the author. In a more recent paper in the same journal, Dr. Ioannidis highlighted the need for balanced review of scientific evidence in the interest of inspiring responsible policy decisions (Ioannidis 2018).

1 fluoride is how consistent it has been in finding significant associations with IQ (Choi et al. 2012). Dr.
2 Chang obscured this by highlighting non-informative studies that made no attempt to measure or
3 investigate prenatal or early postnatal fluoride exposures (Barberio et al. 2017; Broadbent et al. 2015;
4 Morgan et al. 1998; Shannon et al. 1986; Spittle 1998) as being on the same level as, and contradicting,
5 the highly significant findings from the prospective ELEMENT (Bashash et al. 2017) and MIREC
6 (Green et al. 2019) prospective birth cohort studies (pp. 70-71). A particularly poor judgment by Dr.
7 Chang was to place the Spittle abstract on the same level as the ELEMENT and MIREC studies despite
8 the fact that Spittle's abstract does not describe *any* confounder adjustment. Dr. Chang cited the "mixed"
9 nature of the findings as a basis to conclude that the consistency factor has not been met, while failing to
10 acknowledge the inappropriate apples-to-oranges nature of comparing the prospective
11 ELEMENT/MIREC studies to much, much weaker studies.
12

13 114. In her assessment of consistency, Dr. Chang failed to mention the fact that every single
14 prospective birth cohort study with prenatal exposure measurements has found a significant adverse
15 effect of prenatal fluoride on neurodevelopment (Bashash et al. 2017; Bashash et al. 2018; Green et al.
16 2019; Valdez Jimenez et al. 2017). Dr. Chang also gave short shrift to the consistent association between
17 fluoride exposure and reduced IQ reported in the numerous cross-sectional studies (Choi et al. 2012;
18 Duan et al. 2018; Tang et al. 2008). This latter shortcoming may be a result of Dr. Chang's critical
19 misunderstanding of our meta-analysis (Choi et al. 2012), which I will now address.
20

21 115. Dr. Chang claimed that our meta-analysis found an average loss of 0.45 IQ points in the
22 high-fluoride areas and characterizes this as a 10-fold difference with the Tang meta-analysis (Tang et
23 al. 2008). This, however, is not what we reported (see paragraph 78). Because different intelligence
24 scales had been used in the studies considered, we expressed the outcome as a random-effect
25 standardized weighted mean difference estimate, as we clearly explained (Choi et al. 2012). In order to
26
27

1 translate this measure to a difference on the same IQ scale, the joint result must be multiplied by the
2 standard deviation of the IQ scale, i.e., 15. An SMD of -0.45 thus corresponds to a loss of 6.75 IQ
3 points. Contrary to Dr. Chang's mischaracterization, therefore, the results of our meta-analysis are
4 consistent with the Tang meta-analysis, a fact that we actually mention in our published paper (Choi et
5 al. 2012).

6 116. Dr. Chang's assessment of consistency also entirely ignored the findings from
7 occupational studies, as well as the neuropathology data from examinations of fetal brains in endemic
8 fluorosis areas. As I explained in my report, each of these types of studies is consistent with, and provide
9 support for, fluoride being a neurotoxic agent.
10

11 117. *Specificity*: As Kenneth Rothman (2012) and others (Neutra 2018) have emphasized, and
12 as Dr. Chang recognized, lack of specificity between an exposure and an outcome (e.g., asbestos and
13 mesothelioma) does not weigh against or in favor of a causal conclusion.

14 118. *Temporality*: Dr. Chang's assessment of temporality mirrored her assessment of
15 consistency in that she cited the two New Zealand studies as contradicting the findings from the
16 ELEMENT and MIREC cohorts. Once again, Dr. Chang fails to acknowledge the absence of prenatal or
17 early postnatal fluoride exposure assessments in the New Zealand studies, nor any of the other serious
18 shortcomings of these studies. Instead, Dr. Chang focused on non-differential measurement uncertainties
19 of the urine-fluoride data in the far superior ELEMENT and MIREC cohorts to cast doubt on the
20 findings of these studies. As already discussed in my report, however, the imprecision of the fluoride
21 exposure parameters would likely *bias the results toward the null*, not the reverse. The temporality
22 requirement is thus met with fluoride, as each of the prospective birth cohort studies has found a
23 significant association between early-life exposure to fluoride and the offspring's subsequent
24 performance on neurobehavioral testing. The exposure preceded the effect in these studies, which is
25
26
27
28

what the temporality factor is supposed to assess.

119. *Biological Gradient*: The ELEMENT and MIREC studies have reported monotonic dose-response relationships between elevated prenatal fluoride exposure and IQ deficits in the offspring (Bashash et al. 2017, Green et al. 2019), as well as ADHD behaviors (Bashash et al. 2018). Dr. Chang dismissed the biological gradient of these effects by showing scatterplots from the ELEMENT and MIREC cohorts without the trend lines. However, this approach proves little insight, other than illustrating the undisputed fact that there is substantial natural variation in IQ across the population and that an appropriate statistical analysis is needed to extract a reliable estimate of the average effect of the toxicant exposure. Similar scatterplots have been published showing the effects of lead and IQ, as can be seen in the figure to the right (Rothenberg & Rothenberg 2005, Figure 1). Lead would thus fail the biological gradient test that Dr. Chang has used for fluoride. Dr. Chang also argued that outliers may have distorted the effects seen in the ELEMENT and MIREC cohorts (p. 77-78), without acknowledging that statistical analyses on the impact of outliers have been conducted and that the results did not meaningfully change (Bashash et al. 2017).

120. *Plausibility*: Dr. Chang limited her assessment of biologic plausibility to NTP's assessment of learning and memory (NTP 2016) in animal models, and to Dr. Tsuji's expert report. In so doing, Dr.

1 Chang completely ignored the large body of animal literature showing adverse neuroanatomical and
2 neurochemical effects from fluoride exposure, as already reviewed by the National Research Council
3 (NRC 2006) and by Dr. Thiessen in her report. The NRC concluded that the neuroanatomical and
4 neurochemical effects are sufficient to determine that fluoride interferes with brain function (NRC
5 2006). Dr. Chang ignored this information in favor of the NTP's more narrow assessment on
6 learning/memory, but even the NTP assessment found suggestive evidence that fluoride impairs learning
7 and memory. In contrast to Dr. Chang's assessment, EPA's own experts on developmental
8 neurotoxicity, including internationally recognized scientists such as William R. Mundy and Kevin M.
9 Crofton (Mundy et al. 2015), have identified fluoride as a chemical with substantial evidence of
10 developmental neurotoxicity.
11

12 121. *Coherence*: Dr. Chang dismissed the coherence of fluoridated water reducing IQ on the
13 grounds that IQ scores in US children steadily improved throughout the 20th century (the so-called
14 "Flynn Effect"). Dr. Chang even went so far as to suggest that fluoridation may be responsible for the
15 increased scores, although more plausible explanations are known. Under Dr. Chang's simplistic
16 framework, leaded gasoline could not have reduced IQ and may have increased it, as it was introduced
17 in the early part of the 20th century and IQ scores continued to increase during the entire duration of its
18 use. It is well accepted, however, that low-level lead exposure reduces IQ, and thus the Flynn Effect
19 argument—while perhaps superficially appealing—does *not* demonstrate "incoherence."
20

21 122. In her assessment of coherence, Dr. Chang failed to consider other relevant considerations,
22 including the association between neonatal fluoride exposure mediated by infant formula feeding and
23 reduced IQ (Till et al. 2020), as further discussed below. While the studies prior to the recent Canadian
24 analysis did not evaluate the potential role of neonatal fluoride exposure, formula feeding is well
25 established to increase a baby's fluoride exposure, even in areas without fluoridated water (Harriehausen
26
27

et al. 2019; Zohoori et al. 2019). Although other factors are of likely importance, the relationship between formula-feeding and reduced IQ is coherent with maternal fluoride exposure during pregnancy being associated with a lowered IQ in the child and supports a causative relationship between early-life exposure to fluoride and IQ deficits.

123. *Experiment:* Dr. Chang ignored the NRC’s observation (NRC 2006) that case reports of fluoride toxicity constitute “experimental studies” of neurologic symptomatology following fluoride exposure (NRC, p. 208). The case reports involve “one or more individuals who underwent withdrawal from their source of fluoride exposure and subsequent re-exposures under ‘blind’ conditions.” In most cases, the symptoms (which included lethargy, weakness, and impaired ability to concentrate) “disappeared with the elimination of exposure to fluoride and returned when exposure was reinstated.” Although experimental support is not an obligatory criterion (Neutra 2018), the existence of such support should not be missed in what is dubbed a systematic assessment.

124. *Analogy:* I agree with Dr. Chang that “analogies can be drawn to other naturally occurring elements, especially certain metals” like lead (p. 85). As discussed above, many of the exaggerated criteria that she uses to reject a causal relationship between fluoride exposure and IQ could be equally used to erroneously dismiss the causal relationship between low-level lead exposure and IQ.

125. In summary, after correcting for Dr. Chang’s errors and biases in judgment, the Bradford-Hill aspects support, rather than detract from, a causal relationship between fluoride in water and neurotoxicity. After analyzing and considering Dr. Chang’s systematic review, I have more, not less, confidence that developmental neurotoxicity is a serious risk of elevated fluoride exposure.

VIII. BENCHMARK DOSE (BMD) ANALYSIS

A. Selection of Source Data

126. Regulatory agencies are in overall agreement in using Benchmark Dose (BMD) analyses to

1 calculate non-cancer health-based limits for dietary intakes of contaminants, such as those found in
2 drinking water (EFSA 2009; EPA 2012).

3 127. As with the Faroe Islands cohort that the EPA relied upon in its risk assessment for
4 methylmercury, the ELEMENT and MIREC studies are high-quality birth cohorts suitable for dose-
5 response analysis (Bashash et al. 2017; Green et al. 2019). Further, as the data refer to the critical effect
6 in a highly vulnerable population, they constitute appropriate data to use for identifying a safe exposure
7 limit for fluoride. I worked, therefore, with my colleague, Dr. Budtz-Jorgensen, on BMD analyses of
8 these studies, which I describe below.
9

10 128. Our selection of the ELEMENT and MIREC studies for BMD analysis is consistent with
11 an analogous assessment conducted by both Dr. Chang and her colleague, Dr. Joyce Tsuji (Tsuji et al.
12 2015) for another neurotoxicant. In their paper, Drs. Chang and Tsuji sought to determine if the existing
13 RfD for arsenic is adequately protective of neurotoxicity. To answer this question, they conducted a
14 systematic review of the literature to see if there were any studies that would permit a dose-response
15 analysis for quantitative risk assessment. After reviewing the literature, they found a study that, in their
16 judgment, was suitable for the purpose: a study from Bangladesh by Hamadani et al. (2011).
17

18 129. The ELEMENT and MIREC studies are at least equally suitable for dose-response analysis
19 as the one study Dr. Chang and Dr. Tsuji found sufficiently reliable to use for their risk assessment of
20 arsenic exposure. As with the Hamadani study, the ELEMENT and MIREC studies have a (i)
21 prospective birth cohort design; (ii) large sample size; (iii) control for potential confounders;²⁰ (iv) urine
22 measurements²¹ of the toxicant of interest during pregnancy; (v) and extended follow-up (up to 5 years
23

24 ²⁰ Drs. Chang and Tsuji considered studies to have sufficiently controlled for potential
25 confounders if they controlled for SES or HOME Score and parental education/IQ (Tsuji et al. 2015, p.
26 93).

27 ²¹ As with the ELEMENT and MIREC studies, the Bangladesh study measured prenatal
28 exposure through several samples of maternal urine (adjusted for specific gravity) (Hamadani 2011).
The Bangladesh study collected urine twice during the pregnancy (at gestational weeks 8 and 30), which

after birth). In fact, the ELEMENT and MIREC studies have an important advantage: the average arsenic exposure in Bangladesh substantially exceeded exposures in the U.S.,²² which is not the case with the North American fluoride cohort studies.

130. My calculations of benchmark values for fluoride from the ELEMENT and MIREC cohorts are therefore in accordance with the criteria that Drs. Chang and Tsuji have previously used when generating benchmark calculations for arsenic (where adverse effects were seen in girls, but not boys, at 5 years of age).

B. Selection of Benchmark Response (BMR)

131. The benchmark dose (BMD) is defined as the dose that leads to a specific loss (or degree of abnormality) known as the benchmark response (BMR) in the outcome variable. The BMR must be defined before the analysis (EPA 2012), and general guidelines been developed for the selection of a BMR (EFSA 2009).

132. According to the EPA Clean Air Scientific Advisory Committee, a 1-to-2 IQ point reduction at the population level is “highly significant from a public health standpoint,” and should be prevented in up to 99.5% of the population (EPA 2008). Consistent with this, previous BMD analyses of human neurotoxicity have selected 1 IQ point as the BMR (Budtz-Jorgensen et al. 2000; Budtz-Jorgensen et al. 2013; EFSA 2010; Tsuji et al. 2015).

133. Economists have calculated the substantial losses in lifetime incomes from a decrease of 1 IQ point²³ (Gould 2009), as also practiced by economists at the EPA in regulatory impact analyses (EPA 2008).

134. Research on other neurotoxicants (Grandjean 2013) has shown that shifts to the left of IQ is a lower number of samples than the MIREC cohort, and roughly the same as the ELEMENT study.

²² The Bangladesh study addressed a population with mean urinary arsenic levels ranging from 35 to 80 ug/L, which is about 10-to-40 times the levels measured in the US population.

²³ In terms of 2006-dollars, the value of 1 IQ point was calculated to be about \$18,000 (Gould 2009; Spadaro and Rabl 2008).

distributions in a population (i.e., reductions in average IQ) can have substantial impacts, especially among those in the high and low ranges of the distribution (Bellinger 2007).

135. Consistent with prior analyses, including our own, we therefore selected 1 IQ point as the BMR (Budtz-Jorgensen et al. 2000; Budtz-Jorgensen et al. 2013).

C. Analyses of ELEMENT and MIREC Data

136. For our BMD analysis, we used the same formula that we used in our prior assessment of lead (Budtz-Jorgensen et al. 2013). The formula is as follows:

The BMD is defined by

$$f(0) - f(\text{BMD}) = \text{BMR} \rightarrow \text{BMD} = f^{-1}(-\text{BMR})$$

In a linear model, $(Y = \alpha + \beta d + \epsilon)$, from which we get $\text{BMD} = -\text{BMR}/\beta$.

Likewise, the BMDL is defined as a lower one-sided 95% confidence limit of the BMD. In the linear model,

$$\text{BMDL} = -\text{BMR}/\beta_{\text{lower}}$$

where β_{lower} is the one-sided lower 95% confidence limit for β . Information on the (linear) regression coefficients and their standard deviations, from which the confidence intervals can be calculated, is available from the published articles on the two major prospective cohort studies.

137. For the ELEMENT study (Bashash et al. 2017), a linear dose-response model could be used for the effect of urine-fluoride concentrations on both measures of childhood IQ (i.e., the General Cognitive Index (GCI) results at age 4 and IQ results at ages 6-12). In this model, the BMD and BMDL can be calculated based only on the regression coefficient and its precision. In Table 4 of the publication (Bashash et al. 2017), this information is available both for a crude model and for a model A with confounder adjustment. The table below shows the benchmark results for these two models for both the age-4 GCI and school-age IQ.

Table 2. Benchmark dose results (mg/L urine adjusted for creatinine) obtained from the ELEMENT study results (Bashash et al. 2017).

Model	GCI		IQ	
	BMD	BMDL	BMD	BMDL
Crude	0.133	0.085	0.211	0.121
Adjusted	0.159	0.099	0.200	0.130
Read from plot	0.159	0.102	-	-

138. As these calculations are based on assumptions of Gaussian distributions, we checked the validity by scanning the numbers from the plot in the published article. We tentatively used the *WebPlotDigitizer* software to read the plot shown in the published paper (see Figure 1, page 22) (Bashash et al. 2017), to obtain the individual adjusted GCI results for more accurate BMD calculations. Of the original 287 observations, the software provided 286 observations, probably due to two overlapping observations. Thus, missing a single point only, our calculations based on the scanned data should be considered fairly reliable.

139. Using the standard benchmark approach to epidemiological data and a linear dependency, we find that the BMD for GCI is approximately 0.16 mg/L, and that the BMDL is 0.10 mg/L (bottom line of Table 2). These results are in excellent agreement with the results calculated only from the regression data presented in Table 4 of Bashash et al. (2017).

140. To assess the robustness of the calculation, we included a logarithmic conversion of the exposure parameter. We also used a split linear dose-response curve as in one of our previous studies (Budtz-Jorgensen et al., 2013). These sensitivity analyses showed BMD results that deviated only marginally from the calculation using the default linear association. In conclusion, Table 2 shows

reliable BMD results that have been calculated in accordance with standard EPA procedures.

141. We also conducted a BMD analysis of the MIREC data. As with the ELEMENT study, we calculated the BMD and BMDL from the reported regression coefficients and standard deviations, with the assumption of a Gaussian distribution (Green 2019, Table 2). In addition to calculating the BMD and BMDL from the urine-fluoride data (U-F), we also calculated a BMD and BMDL from the maternal fluoride intake data. Our results are shown in the table below:

Table 3. Benchmark dose results (mg/L urine adjusted for specific gravity, or mg estimated daily intake) obtained from MIREC study results on IQ (Green et al. 2019).

Study	Exposure	Sex	BMD	BMDL
MIREC	Maternal U-F	Both sexes	0.51	0.21
	Maternal U-F	Boys	0.22	0.13
	Maternal U-F	Girls	(–)	0.58
	Maternal F intake	Both sexes	0.27	0.15

142. As shown in the above table, the prenatal BMD for girls is not defined when relying on urine-fluoride, but the BMDL is still meaningful and is, as expected, higher than the other estimates obtained. No sex difference was found when relying on estimated fluoride intake.

143. Overall, the results derived from the two studies are comparable. In the ELEMENT study, the BMDL for maternal urine among ~4-year olds is approximately **0.1 mg/L** (both sexes), while in the MIREC study, it is **0.13 mg/L** (boys) and **0.21 mg/L** (both sexes).²⁴ The respective BMDL for the 6-to-12-year olds from the ELEMENT study is **0.13 mg/L**, thus overall approximately 0.15 mg/L. Consistent with these maternal urinary excretion values, the BMDL for maternal fluoride *intake* in the MIREC

²⁴ Based on how the authors reported the data, our BMDL values from the ELEMENT cohort are creatinine-adjusted, while our BMDL values from the MIREC cohort are specific gravity-adjusted.

study is **0.15 mg/day** (both sexes).

IX. ASSESSMENT OF RISK

A. Comparing BMDLs with Current Exposures in Fluoridated Areas

144. As benchmark dose calculations constitute a routine approach applied by the EPA for establishing safe limits on chemical exposure, the above calculations that rely on overall associations between fluoride exposure and cognitive deficits provide a basis for assessing the risk of cognitive deficits from current fluoride exposure levels.

145. Typically, the EPA uses the BMDL to calculate a Reference Dose (RfD) by dividing by an uncertainty factor for the purpose of accounting for variations in human susceptibility. The default value that EPA uses for the uncertainty factor is 10. Here, if we round up the overall BMDL to **0.2 mg/L**, or about 0.2 mg/day, the RfD would likely be 0.02, which is very much below current exposure levels, especially in communities with fluoridation programs (Till et al. 2018). But, *even if no uncertainty factor is applied, and even if relying on the BMD rather than the BMDL* (both of which would be unusual), the RfD would still be well below current exposure levels in fluoridated areas (Till et al. 2018).

146. The serious risk that we are confronted with can be appreciated by visually comparing the BMDLs against documented exposure levels in fluoridated communities. The following Figure 2A, adapted from Green et al. (2019), compares an overall BMDL for maternal urine-fluoride (0.15 mg/L) with the maternal urine-fluoride concentrations reported in the study. As can be seen, the urine-fluoride levels far surpass the levels associated with IQ loss.

Figure 2A. Distribution of Maternal Urinary Fluoride

Adapted from Green et al 2019, Figure 2.

A Maternal urine

147. The below Figure 2B compares the approximate BMDL for maternal fluoride *intake* from beverages (0.15 mg/day) against the reported fluoride intakes in Green et al (2019). As can be seen, the estimated fluoride intakes in fluoridated areas far surpass the fluoride intake level associated with a clear IQ loss.

148. There are no contemporary large-scale studies of urine-fluoride concentrations in the United States, as the CDC has not yet reported urinary fluoride excretion levels as part of its ongoing National Health and Nutrition Examination Survey (NHANES) studies. One can reasonably infer, however, that urinary fluoride excretion levels in fluoridated areas of the U.S. are generally comparable to those in fluoridated areas of Canada. The reasonableness of this inference is supported by the following facts:

149. Canada and the U.S. add fluoride to water to reach the same target concentration (0.7 mg/L), although empirical data suggests Canadian cities only reach 0.6 mg/L which is slightly less than the U.S. (Till et al. 2018).

150. Fluoridated water is recognized as the largest source of fluoride exposure for adults, particularly when indirect sources are accounted for, such as beverages and foods prepared with the

water, including commercially prepared beverages such as soda and reconstituted juice (EPA 2010).

151. Urine-fluoride has been shown to be a good indicator of total daily fluoride intake, and has a close, linear correlation with the fluoride content in water (Villa et al. 2000; McClure 1944; Smith et al. 1950).

152. The largest study of urine-fluoride levels in the U.S. found that pooled urine samples from healthy young males generally mirrored the fluoride concentration in the drinking water (McClure 1944). Based on U.S. data, therefore, a person drinking water with 0.7 mg/L fluoride would be expected to have about 0.7 mg/L in their urine, which is similar to what was found in the MIREC cohort (Till et al. 2018). Although these U.S. data were published prior to widespread fluoridation, the levels today would, if anything, tend to be *higher* today, not lower because fluoride is now available from more sources than was the case in the 1940s (e.g., including commercial beverages made with fluoridated water, dental products, etc.).

153. To address the lack of contemporary US data on fluoride exposures in pregnant women,²⁵ the recent UCSF study measured the concentrations of fluoride in urine (and blood²⁶) of 48 pregnant women living in fluoridated and non-fluoridated areas of California. As with the Canadian study, the UCSF team had the urine tested by Dr. Angeles Martinez-Mier at the University of Indiana and adjusted the fluoride measurements for specific gravity. The study found an average (specific gravity-adjusted) urine-fluoride concentration of **0.69 mg/L** among pregnant women in areas with at least 0.7 mg/L in the community water, which is clearly in the same range as the MIREC team found in Canada (Uyghurturk

²⁵ As noted by the UCSF team, there is only one prior published study of urine-fluoride levels among pregnant women in the US: this is the study by Shen & Taves (1974) that I discussed in my expert report. This study found an average of 1.02 mg/L in maternal urine among a group of 16 pregnant women, but the authors did not report the concentrations of fluoride in water.

²⁶ The study found an average of 0.021 mg/L fluoride in the blood (=1.1 µmol/L) of the women from fluoridated areas (~0.8 mg/L), which is higher than the predicted value (0.015 mg/L = 0.8 µmol/L). As discussed by the NRC, it has been historically estimated that adult populations will have 1 µmol/L in their blood for each 1 mg/L of fluoride in the water (NRC 2006).

2020, Table 2). While the small-scale nature of the study likely introduced some random scatter in the results of the UCSF study,²⁷ the study supports the general similarity in fluoride exposures in the Canadian and U.S. populations.

154. Finally, the relevance of the Canadian IQ data (Green et al., 2019) to the US can be appreciated by comparing the BMDL to the maternal urine-fluoride concentrations reported by the UCSF team (Uyghurturk 2020). As can be seen in the following Figure 3, maternal urine-fluoride concentrations found in pregnant women in the Californian cohort greatly exceed the BMDL for fluoride-associated IQ loss. This, ultimately, is the most important consideration.

²⁷ The study found some high levels of urine-fluoride in the mid-range fluoride communities (0.3-0.5 mg/L), which slightly skewed the distribution (Uyghurturk 2020, Fig. 2). As the authors note, this may be the result, in part, of the fact that the women had their urine tested while visiting a clinic in San Francisco, which is fluoridated (Uyghurturk 2020, p. 6-7). In the areas with >0.3 mg/L in water, the average (specific-gravity adjusted) fluoride level was 0.74 mg/L (Uyghurturk 2020, Table 5).

B. Comparing Fluoride's Population-Level Effects with Other Causes of IQ Loss

155. In order to compare fluoridation's population-level effects with other neurotoxicant exposures, some approximate estimates of fluoride-associated IQ losses can be made. The calculations rely on several assumptions that are necessary in the absence of actual data and are therefore meant only to identify relative orders of magnitude. On the conservative side, I shall assume that all children are equally vulnerable and that the dose-dependent IQ losses observed in the recent prospective studies can be used to assess the impact on the population at large (i.e., that genetic and other predisposition can be ignored).

156. My analysis focuses on the average difference in maternal urine-fluoride levels between fluoridated and non-fluoridated areas. The Canadian study (Till et al. 2018) showed that this difference is approximately 0.4 mg/L. It bears emphasizing that this difference likely understates the true contribution of fluoridated water because part of the exposure in "non-fluoridated" areas comes from the "halo" effect. The halo effect refers to the fact that many commercial beverages and foods made in fluoridated areas are shipped to and consumed in non-fluoridated areas and that residents from non-fluoridated communities may work or spend time in fluoridation areas.²⁸

157. Given the BMD results, an average increase of 0.4 mg/L in maternal fluoride concentrations is above the threshold for developmental neurotoxicity, even if assuming a zero background exposure. Using the dose-dependent losses observed in the recent prospective studies (Bashash et al. 2017; Green et al. 2019), this elevated exposure will correspond to an IQ loss of approximately 2 IQ points.

158. Because about two-thirds of the U.S. population receives fluoridated drinking water, one can assume that a similar proportion of the 4 million annual U.S. births (i.e., more than 2.5 million

²⁸ This widespread dispersal of fluoridated water in commercial products helps to explain the relatively high urine-fluoride levels now seen in non-fluoridated communities versus the situation back in the 1940s (Till et al. 2018).

1 births) are affected by fluoridation-associated exposure increases. With the 2-point average IQ loss
2 associated with fluoridation, the 2.5 million births will lose a total estimated number of 5 million IQ
3 points annually.

4 159. This approximate estimate can be compared with calculations made by Professor David
5 Bellinger on IQ losses due to major pediatric diagnoses affecting 0-to-5-year-old children (Bellinger
6 2012). According to CDC data and Bellinger's calculations, the top pediatric etiologies for IQ loss are
7 preterm birth at 34 million IQ points lost and lead exposure representing 23 million IQ points lost. For
8 fluoridation, the estimate for children aged 0 to 5 years is approximately 25 million IQ points. Even if
9 this estimate is somewhat imprecise, and unevenly distributed, the order of magnitude is likely to be
10 correct and is very considerable.

12 160. Finally, even if we assume that a threshold exists at approximately 0.8 mg/L in maternal
13 urine (as suggested by mere inspection of the IQ plots in the ELEMENT study for the 6-to-12-year-old
14 cohort members), water fluoridation would still result in substantial IQ losses. As documented in the
15 MIREC study, the 75th percentile maternal urine-fluoride levels (adjusted for creatinine) are 1.04 mg/L
16 in the fluoridated areas versus 0.52 mg/L in the non-fluoridated areas (Till et al. 2018, Table S4). In
17 fluoridated areas, pregnant women above the 75th percentile are already at least 0.29 mg/L above the
18 hypothetical threshold, and thus 25% of the children would then experience an average IQ loss of at
19 least 1.5 points. This would amount to over 4.5 million lost IQ points among 0-to-5-year-olds. Even this
20 smaller amount of IQ losses exceeds the IQ losses attributed to methylmercury exposure in the U.S.
21 (Grandjean et al. 2012).

23 161. I have made these calculations only to illustrate the significance and impact of
24 neurotoxicity outcomes from fluoridation exposures, and I offer these crude estimates to emphasize my
25 concern that developmental neurotoxicity due to early-life exposure to fluoride is a serious public health
26

1 hazard with substantial societal impacts that must be controlled.

2
3 **X. CONCLUSIONS**

4 162. Recent research has shown that the most vulnerable life stage for many toxicants,
5 particularly those that adversely affect the brain, is during intrauterine and early postnatal development.
6 Fluoride fits into this paradigm, and efforts to control human fluoride exposures must therefore focus on
7 pregnant women and small children.

8 163. Research on fluoride-exposed workers and laboratory animals suggest that elevated
9 fluoride exposure is toxic to the brain and nerve cells. Epidemiological studies have identified links to
10 learning, memory, and intelligence deficits, though most of the past studies focused on populations with
11 fluoride exposures higher than those typically provided by U.S. water supplies.

12 164. Epidemiology studies of birth cohorts from the most recent years document that adverse
13 effects on brain development happen at elevated exposure levels that occur widely in North America, in
14 particular in communities with fluoridated drinking water. These new prospective studies are of very
15 high quality and show very similar results, thus leaving little doubt that developmental neurotoxicity is a
16 serious risk associated with elevated fluoride exposure. This evidence shows that community water
17 fluoridation is associated with IQ losses that are substantial and of economic and societal concern.

18 165. Applying methods for standards setting routinely used by the EPA (i.e., Benchmark Dose
19 analysis), the recent studies on IQ deficits in children allow the estimation of a recommended limit that
20 would protect against neurotoxicity. Such calculations show that current allowable limits for fluoride in
21 drinking water and the levels of fluoride added in community water fluoridation programs both greatly
22 exceed a science-based limit that would protect against developmental neurotoxicity.

23 166. The evidence on fluoride neurotoxicity in the general population is fairly recent and
24
25
26
27

1 unlikely to represent the full toxicological perspective, including adverse effects that may occur at
2 longer delays. As has been seen on numerous occasions, the evidence available today may well
3 underestimate the true extent of the fluoride toxicity. With a reasonable degree of scientific certainty, I
4 therefore consider the elevated levels of fluoride exposure in the U.S. population as a serious public
5 health concern.

6
7 I declare under penalty of perjury, under the laws of the United States, that the foregoing is true
8 and correct to the best of my knowledge and belief.

**CURRICULUM VITAE OF
PHILIPPE GRANDJEAN, MD, DMSc**

PHILIPPE GRANDJEAN, M.D.

Office address

Institute of Public Health
University of Southern Denmark
Winsløwparken 17
DK-5000 Odense C, Denmark
Tel. (+45) 6550.3769
Fax (+45) 6591.1458
Email: pgrand@health.sdu.dk
<http://www.sdu.dk/staff/PGrandjean.aspx>

Harvard School of Public Health
Department of Environmental Health
665 Huntington Avenue
Building 1, room 1312
P.O. Box 15697
Boston, MA 02115
Tel: 617-384-8907
Fax: 617-384-8994
Email: Pgrand@hsph.harvard.edu
<http://www.hsph.harvard.edu/faculty/philippe-grandjean/>

Academic degrees

1974, M.D., University of Copenhagen
1975, Diploma in basic medical research, University of Copenhagen
1979, D.M.Sc. (dr.med.), University of Copenhagen

Chronology of employment

1974-1975	Postgraduate training fellowship, University of Copenhagen
1975-1978	Research fellow, Institute of Hygiene, Univ. Copenhagen
1978-1980	Senior research fellow, University of Copenhagen Visiting fellow, Department of Community Medicine, Mount Sinai School of Medicine, New York
1980-1982	Director, Department of Occupational Medicine, Danish National Institute of Occupational Health
1982-	Professor of Environmental Medicine, Odense University
1983-2017	Consultant in Toxicology, Danish Health Authority
1994-2002	Adjunct Professor of Public Health (Environmental Health) and Neurology, Boston University School of Medicine, Boston
2003-	Adjunct Professor of Environmental Health, Harvard T.H. Chan School Public Health, Boston

Awards and honors

Prize essay in medicine, University of Copenhagen (1972)
Fulbright senior research scholarship (1978)
Keynote speaker, Odense University anniversary (1983)
Gitlitz Memorial Lecture, Association of Clinical Scientists, USA
(1985)

Fellow, Collegium Ramazzini (1987)
Knight of the Dannebrog, awarded by the Queen of Denmark (1990)
The Dannin prize for medical research (1991)
Fellow, American Association for the Advancement of Science (1994)
Irish Congress Lecturer, Royal College of Physicians of Ireland and
Irish Society of Toxicology (1996)
Knight of the Dannebrog, First Degree, awarded by the Queen of Denmark
(2003)
'Mercury madness award' for excellence in science in the public
interest from eight US environmental organizations (2004)
Emeritus Fellow, International Union of Pure and Applied Chemistry,
IUPAC (2009)
Honorary Research Award, International Order of Odd Fellows (2010)
Science Communication Award, University of Southern Denmark (2012)
Bernardino Ramazzini Award (2015)
Basic & Clinical Pharmacology & Toxicology Nordic Award (2015)
Margrethegaarden honorary prize (2016)
John R. Goldsmith Award, International Society for Environmental
Epidemiology (2016)

Editorial boards

American Journal of Industrial Medicine (1987-2017)
Applied Organometal Chemistry (1985-1991)
Arbejdsmiljø (Occupational Environment, in Danish, 1983-1990)
Archives of Environmental Health (European Editor, 1986-1992)
Archives of Toxicology (1987-)
Biomarkers (1996-2001)
Central European Journal of Occupational and Environmental Medicine
(2015-)
Critical Reviews in Toxicology (1985-2012)
Danish Medical Bulletin (1994-2003)
Environmental Health (Editor-in-Chief, 2002-)
Environmental Health Perspectives (2003-)
Environmental Research (1981-1994 and 2014-2017, Associate Editor,
1995-2014)
Industrial Health (2000-2005)
International Journal of Hygiene and Environmental Health (2001-)
International Journal of Occupational and Environmental Health (1994-
2011)
International Journal of Occupational Medicine & Environ Health (1991-
Journal of Clean Technology, Environmental Toxicology, and
Occupational Medicine (1992-1998)
Journal of Environmental Medicine (1998-1999)
Naturens Verden (Natural Science, in Danish) (1987-1991)
Ugeskrift for Læger (Danish Medical Journal, in Danish) (1991-2007)

Scientific societies

American Association for the Advancement of Science (Fellow, 1994)
American Public Health Association
Collegium Ramazzini (Fellow, 1987; Member of the Council, 2005-2013)
Danish Medical Association

Danish Societies of Clinical Chemistry, Epidemiology, Occupational and Environmental Medicine, and Public Health
Faroese Society of Science and Letters
International Society for Environmental Epidemiology

Teaching experience

Professor of Environmental Medicine, Odense University (University of Southern Denmark) (1982-). Member of curriculum committee.

Coordinator, Global Health class.

Adjunct Professor of Public Health (Environmental Health) and Neurology, Boston University School of Medicine, Boston (1994-2002)

Adjunct Professor of Environmental Health, Harvard T.H.Chan School of Public Health, Boston (2003-)

Invited teacher, École des hautes études en santé publique (EHESP, French school of public health) (2009-)

International: Numerous teaching assignments, including guest lectures at universities and related tasks, e.g. as external examiner, National University of Singapore (1995). External evaluator of PhD theses from other universities, including University of Sydney and University of South Pacific (Fiji).

Research support as Principal Investigator since 2000

2000-2006 NIEHS

Mercury associated neurobehavioral deficit in children

2001-2003 Nordic Arctic Research Programme (NARP)

Changing patterns of biomagnified pollutants in the northern marine environment

2001-2004 Danish Medical Research Council

Exposure assessment for endocrine disruptors

2002-2004 Danish Medical Research Council

Environmental epidemiology research

2003-2004 European Commission

Assessment of Neurobehavioral Endpoints and Markers of Neurotoxicant Exposures (ANEMONE)

2003-2005 Danish Medical Research Council

Research in hormone related substances

2003-2006 NIEHS ES11687

Effects of perinatal disruptors in children

2003-2007 EPA STAR RD-83075801-0

Children's vulnerability to environmental immunotoxicant

2004-2011 NIEHS ES12199

Epidemiology of immunotoxicant exposure in children

2006-2011 NIEHS ES13692

Health effects of lifetime exposure to food contaminants

2006-2012 NIEHS ES14460

Three-generation human study of reproductive effects of marine food contaminants

2008-2012 Danish Council for Strategic Research

Environmental pollutant impact on antibody production against current and new childhood vaccines

2007-2013 NIEHS ES009797

Mercury associated neurobehavioral deficit in children

2011-2017 NIEHS ES012199

Epidemiology of immunotoxicant exposure in children

2012-2020 NIEHS ES021993 and NSF OCE-1321612

Immunotoxicity in Humans with Lifetime Exposure to Ocean Pollutants

2013-2019 NIEHS ES021477

Glucose Metabolism in Adults Prenatally Exposed to Diabetogenic Pollutants

2013-2018 NIEHS ES021372

Pollutant-related diabetes in the Nurses' Health Study II

2014-2020 NIEHS ES023376

Gut Microbiome in Adults with Early Life Exposures to Environmental Chemicals

Major Current Funding as Principal Investigator

2017-2020 NIEHS ES026596

Inflammation and metabolic abnormalities in pollutant-exposed children

2017-2022 NIEHS P42ES027706

Sources, Transport, Exposure and Effects of PFASs (STEEP)

2019-2024 ATSDR TS000313

Assessment of PFAS exposures and health effects in two Massachusetts communities with PFAS drinking water contamination

2019-2023 NIEHS ES030394

Vulnerability During Infancy to Immunotoxic Contaminant Exposures

Major committees, boards and elective offices

Danish:

Danish Medical Association: Member, Prevention Council (2011-2014)

Danish Medical Research Council: Consultant on environmental medicine (1985-1990); Member, Joint Research Council Committee on Environmental Research (1986-1991); Member of DMRC (1992-1998)

Danish Society of Community Medicine: Secretary (1977-1978)

Danish Society of Industrial Medicine: Board Member (1974-1983)

Ministry of Education: Member, Committee on Toxicology (1984-1986); Member, Committee on Environmental Education (1986-1987)

Ministry of the Environment: Member, Council on Environmental Chemicals (1983-1989); Member, Environmental Appeal Board (1986-2010); Member, Environmental Research Council (1990-1992); Member, Advisory Committee on Pesticide Research (1995-2004 and 2018-2020); Member, Advisory Committee on Arctic Research (1996-2004)

Ministry of Health: numerous committee appointments; Chair, Committee on Risk Perception (2000-2001)

Ministry of Labour: Consultant on Occupational Health, Council on Occupational Safety and Health (1983-1993); Member, Occupational Health Council Research Committee (on behalf of the Danish Medical Research Council) (1984-1990 and 1999-2003)

Ministry of Research: Chair, Committee on Research at the Faroe Islands (1995-1996); Member, Committee on Scientific Dishonesty (2004-2006); Chair, Program Committee on Non-Ionizing Radiation (2004-2009)

Odense University (from 2000 University of Southern Denmark), elected

offices: Chairman, Institute of Community Health (1982-1985; 1996-1999); Member of Executive Committee, Institute of Community Health (from 2000 Institute of Public Health) (1986-1995; 2000-2005); Member, Faculty Research Committee (1983-1985); Member, Curriculum Committee (1984-1986); Member, Faculty Council (1985-1993); Vice-Dean (1991-1993); Member, Scientific Integrity Committee (2003-2022)

United States and international:

Academy of Finland: member of panel evaluating the National Institute of Public Health (1995), site visit of center of excellence (2001)

Agency for Toxic Substances and Disease Registry: Workshop Rapporteur, Neurobehavioral Test Batteries for Use in Environmental Health Field Studies (1992); Member, Expert Panel of Mercury (1998)

Association of Schools of Public Health in the European Region: Treasurer (1975-1977)

BioMedCentral: Member, Editors Advisory Group (2011-2013)

Boston Environmental Hazards Center: Consultant (1994-1999)

Collegium Ramazzini: President, International Conference, The precautionary principle: Implications for research and prevention in environmental and occupational health (2002); Member, Executive Council (2005-2013)

Commission of the European Communities: National Expert, Working Party on Environmental and Lifestyle-Related Diseases (1988-1990); ad hoc Consultant for evaluation of research applications; ad hoc Scientific Advisor on Risk Assessment (2009-); Member, Scientific Committee on Emerging and Newly Identified Health Risks; - Working group on Dental Amalgam (Human Health)(2012-2013)

European Environment Agency: Member, Scientific Committee (2012-2020)

European Food Safety Authority: Member, Panel on Contaminants in the Food Chain responsible for 85 opinions (2003-2009); Member of Working Groups on mercury, polychlorinated biphenyls, cadmium, lead, and benchmark dose

Food Advisory Committee, U.S.FDA, Methylmercury: invited expert (2002)

INMA (Infancia y Medio Ambiente), Spain: Member, Project Steering Committee (2010-)

Institut de Recherche Santé, Environnement et Travail, France: Member, Board of Advisers (2015-)

International Agency for Research on Cancer: Member of Task Group, Monographs on the Evaluation of Carcinogenic Risks to Humans, Vol. 47 (1988), Vol. 49 (1989), as chairman, Vol. 58 (1993), and as Subgroup chair, Vol. 100C (2009)

International Commission on Occupational Health: Danish Delegation Secretary (1982-90); Member, Scientific Committee on the Toxicology of Metals (1987-); Member of the Board (1990-1996)

International Programme on Chemical Safety: Member of Task Group, Environmental Health Criteria, Vol. 36 (1984) and 72 (1986)

International Society for Environmental Epidemiology: Councillor (1991-1994)

International Union of Pure and Applied Chemistry: Member, Subcommittee on the Toxicology of Nickel (1979-1989); Titular

Member (1985-1991) and Chairman (1987-1991), Commission on Toxicology; Chairman, Subcommittee on Risk Assessment (1985-1989)
Instituto de Saude Ambiental, Lisboa, Portugal: Member, External Advisory Committee (2018-2020)
Karolinska Institute (Stockholm, Sweden): Member of international evaluation panel on environmental medicine (1993)
Ministry for Scientific Policy (Belgium): Consultant on national research program on health hazards (1990 and 1994)
National Institutes of Health (USA): Member of Special emphasis panels (2009-)
NATO Priority Area Panel on Environmental Security: Member (1996-1997)
Norwegian Research Council: ad hoc reviewer (2001-2008); Chairman of Environment and Health Review Group (2009-2010); member of steering committee (2011-2015)
Prenatal Programming and Toxicity (PPTOX) conferences: Organizer/Chair/Co-chair, Torshavn (2007), Miami (2009), Paris (2012), Boston (2014), Kita-Kyushu (2016), Torshavn (2018)
Society of Occupational and Environmental Health: Member, Governing Council (1990-1993)
Swedish Council for Work Life Research: Member, Priority Committee on Chemical Health Risks (1997-1998)
U.N.Environment Programme: Member, Global Mercury Assessment Working Group (2002)
U.S. Environmental Protection Agency: Member, SAB/SAP Endocrine Disruptor Screening Program Subcommittee (1998-1999); Member, Food Quality Protection Act (FQPA) Science Review Board (SRB)(1999-2003)
White House Office of Science and Technology Policy: Team leader and presenter, Workshop on Scientific Issues Relevant to Assessment of Health Effects from Exposure to Methylmercury (1998)
World Health Organization: Temporary Adviser or Consultant on several occasions, five times elected Rapporteur; Member, European Advisory Committee on Health Research (2011-2017)

I, Howard Hu, MD, MPH, ScD, declare that:

1. I am a physician-scientist trained in internal medicine, occupational/environmental medicine, epidemiology and general public health who has held leadership positions in science and academia for over 2 decades.

2. I am also the Principal Investigator of ongoing research that is examining the impact of early-life exposures to fluoride on neurobehavioral development in the offspring participating in the Early Life Exposures in Mexico to Environmental Toxicants (ELEMENT) project.

I. SUMMARY OF QUALIFICATIONS

3. A complete summary of my qualifications and publications can be found in my Curriculum Vitae, which has been marked as Plaintiffs' Exhibit 5 and attached herein.

4. As relevant to my testimony here, I am an epidemiologist with decades of research experience investigating the impact of environmental toxicants on human health. In 1990, I received a Doctor of Science degree in Epidemiology from the Harvard School of Public Health, and since that time have taught epidemiology at Harvard, University of Michigan, and University of Toronto, where I served as Dean of the School of Public Health.

5. I hold editorial positions on leading environmental and occupational health journals, including the *American Journal of Industrial Medicine*, *Current Environmental Health Reports* and *Environmental Health Perspectives*, and serve as a peer reviewer for the *American Journal of Epidemiology*, *Epidemiology*, *Journal of the American Medical Association*, *Lancet*, *New England Journal of Medicine*, and *Pediatrics*, amongst others.

6. My own epidemiological research has resulted in hundreds of peer-reviewed publications in leading scientific journals. For the past 29 years, this research has been continuously funded by the National Institutes of Health (NIH) through a number of competitive R01 grants.

1 7. The Environmental Protection Agency (EPA) has funded several of my epidemiological
2 studies, including a \$7.8 million research grant to study the effects of metals mixtures on children's
3 health. I have also served as an expert advisor to the EPA, including as a member of EPA's Science
4 Advisory Board on Relative Risk Reduction Strategies and as an expert reviewer of EPA's recent draft
5 report on the concentration-response functions between lead exposure and cardiovascular disease.

6 8. In 1993, I co-founded the ELEMENT research project, a pregnancy and birth cohort that
7 has been funded by both the EPA and NIH. Since its inception, ELEMENT has evolved into a highly
8 successful, award-winning project involving collaborators at the University of Michigan, Harvard, and
9 other academic institutions in the U.S., Canada, and Mexico.

10 9. Through the ELEMENT cohort, we have studied how prenatal exposure to environmental
11 toxicants—including lead, mercury, and fluoride—affect children's health, including their
12 neurodevelopment. Thus far, the ELEMENT cohort has generated over 80 high-impact publications and
13 provided evidence contributing towards environmental health policies around the world, including the
14 EPA's national air standard for lead and the CDC's "Guidelines for the Identification and Management
15 of Lead Exposure in Pregnant and Lactating Women."

16 10. In 2012, following the National Research Council's (NRC) call for more research to
17 investigate the neurobehavioral risks of fluoride exposure, the team I lead successfully competed for a
18 peer-reviewed NIH RO1 grant to study the neurodevelopmental effects of pre- and post-natal fluoride
19 exposures. This research was funded with an understanding that it would provide a major contribution to
20 fluoride risk assessment and policy decision-making on the neurotoxicity concerns identified by the
21 NRC.

22 11. To date, my team has published five peer-reviewed studies on fluoride, including two
23 prospective studies on fluoride and neurodevelopment that were published in the world's two most
24
25
26
27
28

1 prominent environmental health journals: *Environmental Health Perspectives* and *Environment*
2 *International* (Bashash 2017, Bashash 2018, Cantoral 2019, Liu 2019, Thomas 2016). As with our own
3 research, the journal *Environmental Health Perspectives* is funded by the NIH.

4 **II. SUMMARY OF OPINIONS**

5 12. The ELEMENT prospective cohort studies of fluoride's neurodevelopmental effects are
6 methodologically rigorous studies that provide scientifically reliable and robust results.

7 13. The results of the ELEMENT prospective cohort studies are consistent with and support
8 the conclusion that fluoride is a developmental neurotoxicant at levels of exposure seen in the general
9 population in water-fluoridated communities.
10

11 **III. BASIS FOR OPINIONS**

12 **A. The Methodological Strengths of the ELEMENT Studies**

13 14. ***Prospective Birth Cohort Study Design:*** One of the key strengths of our ELEMENT
14 research is that it has utilized a prospective birth cohort design. Prospective studies (aka longitudinal
15 cohort studies designed at the outset to enable research on the topics of interest and that follow a defined
16 group of individuals) are recognized by epidemiologists as the ideal study design for investigating the
17 impact of environmental toxicants on human health, in part, because the measurement of exposure
18 precedes the development of disease/dysfunction. This is important because it permits greater
19 confidence in the causal relationship of an association since the requirement of temporality is satisfied
20 i.e., the exposure precedes the effect, which, in turn, is one of the components of the Bradford Hill
21 criteria. Where there is suspicion that a chemical may exert a toxic effect *in utero*, a birth cohort study
22 design is critical because it allows an assessment of exposure during the prenatal period.
23

24 15. ***Effective Control for Other Factors that Influence IQ:*** Our ELEMENT studies have
25 considered and controlled for a large number of factors known to affect neurodevelopment, which
26
27

increases the rigor of the results. First, we excluded women from the study who had characteristics known to affect neurodevelopment, including gestational diabetes, renal disease, hypertension, circulatory diseases, use of illicit drugs, and alcohol consumption. Second, our analyses of fluoride and neurodevelopment controlled for a large number of potential confounders, including maternal age, maternal education, maternal IQ, birth weight, gestational age at time of delivery, sex of child, birth order, maternal smoking, and marital status. Third, we performed sensitivity analyses which controlled for the quality of the child's home environment (i.e., HOME),¹ as well as prenatal lead and mercury exposures.

16. ***Blinded Assessments:*** Our studies employed a "blinded" study design where neither the examiners nor the subjects were aware of the subject's fluoride exposure status at the time of the neurodevelopmental exams. A blinded study design is superior to a non-blinded study because it helps protect against bias, including unconscious bias, in the assessment.

17. ***Individual Biomarkers of Both Prenatal and Postnatal Exposure:*** As cohort studies, our investigations have collected and utilized individual measurements of fluoride exposure, covariates, and the outcomes of interest. Cohort studies with individual measurements of exposure, covariates and outcomes are considered much more robust than studies with group-level metrics (otherwise known as "ecological studies") because the accuracy and precision of individual-level measures are far superior to the estimates of these parameters that are associated with ecological studies. In our studies, we measured prenatal fluoride exposure by testing archived samples of the mother's urine that were collected during pregnancy. Urine fluoride is a well-accepted biomarker of total fluoride exposure. As the EPA has

¹ The HOME Score is a rating that is performed by a research observer who gains permission to enter the home and observe the interactions between the offspring and other family members, as well as other characteristics of the home environment. It is intended to try to capture the ability of the home to enrich a child's educational development and skill development. It is often highly correlated with socio-economic status, but it also has some independent value of its own in determining a child's neurodevelopmental trajectory.

1 recognized, “archives of biological samples from birth cohort studies . . . provide critical information on
2 the prenatal and childhood determinants of adult disease” (EPA-NIEHS 2017, p. 9). The archived urine
3 samples in our studies were tested under the oversight and direction of Dr. Angeles Martinez-Mier, a
4 leading authority on the measurement of fluoride in urine and plasma.

5 18. As I acknowledge and discuss further below, there are some limitations with our urine-
6 based exposure estimates. These limitations, however, do not provide a plausible explanation for the
7 results we have observed as they create *non-differential* imprecision in the exposure variable (in this
8 case, the non-differential exposure misclassification is sometimes referred to as “random” or “classical”
9 measurement error associated with exposure). It is a basic epidemiologic axiom that non-differential
10 errors, such as non-differential exposure misclassification, bias the results towards the null (i.e., no
11 association exists), rather than create spurious associations where none otherwise exist. I discuss this
12 further below.
13

14 19. ***Large Cohort Sizes:*** Our studies have involved a sufficiently large number of mother-
15 offspring pairs to permit statistical analyses that are stable and robust. In our 2017 study (“Bashash
16 2017”), we investigated fluoride’s relationship with intelligence among 299 mother-offspring pairs. This
17 included 287 mother-offspring pairs for the analysis of intelligence at age 4, and 211 mother-offspring
18 pairs for an analysis of intelligence at ages 6-12. In our 2018 study (“Bashash 2018”), we investigated
19 the relationship between fluoride and symptoms of Attention-Deficit Hyperactivity Disorder (ADHD)
20 among a total of 213 mother-offspring pairs, with the ADHD assessment conducted between the ages of
21 6 and 12.
22

23 20. ***Reliable Neurocognitive Tests:*** Our 2017 study on intelligence used validated,
24 standardized neurocognitive tests that were administered by a team of psychologists. For the 4-year old
25 children, we used the McCarthy Scales of Children’s Abilities (MSCA), and focused on the General
26
27

Cognitive Index (GCI) score. For the 6-12 year old children, we used the Spanish version of the Wechsler Abbreviated Scale of Intelligence (WASI)² to assess Full-Scale IQ. All raw scores were standardized for age and sex. The examining psychologists were trained and supervised by an experienced developmental psychologist, and independent testing confirmed a very high correlation (0.99) in the scoring, thus confirming a high degree of inter-examiner reliability.

21. **Reliable Neurobehavioral Tests:** Behaviors associated with ADHD were assessed using the Spanish version of the Conners' Rating Scales-Revised (CRS-R)³ and Conners' Continuous Performance Test (CPT-II, 2nd Edition).⁴ All measures of ADHD-behaviors were standardized for age- and sex. Higher T-scores (mean of 50, SD of 10) indicate poorer performance. All psychometric tests were applied under the supervision of an experienced psychologist.

22. **Appropriate Statistical Analyses that Did Not Assume Linearity:** We used the same standard statistical analyses for our fluoride studies as we have used for our other ELEMENT studies. These included regression analyses that appropriately adjusted for potential confounders, as well as Generalized Additive Models (GAM) that visualized adjusted associations between fluoride and neurodevelopment for purposes of assessing the linearity of the relationship. We did *not* assume

² The WASI shows strong criterion validity with the full-length Wechsler Intelligence Scale for Children (WISC-III; ages 6-16 yrs), and the Wechsler Adult Intelligence Scale (WAIS; ages 16+ yrs). The correlation coefficient between the Full Scale IQ of the WASI and WISC-III is 0.81 (Wechsler, 1991), and 0.92 between the WASI and the WAIS-III (Wechsler, 1999), indicating a high covariance between the abbreviated and full-length measures of intellectual ability. The WASI is also correlated with another abbreviated IQ test, the Kaufman Brief Intelligence Test ($r = 0.89$), providing evidence for convergent validity (Hays et al., 2002). Finally, the WASI demonstrates excellent internal consistency (reliability=0.976) (based on data from Tables 5.1 and 5.8 of the WASI manual).

³ The CRS-R contains three ADHD scales that correspond with the Diagnostic and Statistical Manual of Mental Disorders – 4th edition (DSM-IV) criteria for ADHD: 1) DSM-IV Inattention Index, 2) DSM-IV Hyperactive-Impulsive Index, and 3) DSM-IV Total Index (inattentive and hyperactive-impulsive behaviors combined). It also examines seven types of behavior problems that were derived through factor analysis, including: Oppositional, Anxious-Shy, Cognitive Problem/Inattention, Hyperactivity, Perfectionism, Psychosomatic, and Social Problems. For our study, we examined the three DSM-IV ADHD scales as our primary outcomes because these scales are intended to screen for ADHD, and are commonly used to study the association between diverse environmental contaminants and ADHD- behavior problems.

⁴ The CPT-II is a computer-administered signal detection paradigm. Using the CPT-II, we measured errors of omission and commission, and hit reaction time (response latency).

linearity in the dose-response relationship. Additionally, we took appropriate steps to eliminate the influence of outliers and influential points.

B. Prenatal Fluoride Exposure Is Associated with Substantial and Significant Adverse Effects on IQ and ADHD-Behaviors in the ELEMENT Cohort

23. In the ELEMENT cohort, we found that prenatal fluoride exposure has a linear, dose-response relationship with reduced IQ among both 4-year old and 6-12 year old children (Bashash 2017).⁵ In our main model that adjusted for potential confounders, we found that each 0.5 mg/L increase in maternal urinary fluoride (which approximates the interquartile range, i.e., the difference between the 25th v. 75th percentile) was significantly associated with a loss of 3.15 GCI points among the 4-year-olds, and a loss of 2.5 IQ points among the 6-to-12 year olds. These are substantial reductions in intelligence that rival the effect sizes associated with lead exposure. As one measure of practical impact developed and published in 2009 by an expert from the Economics Policy Institute, each IQ point lost due to lead exposure was estimated to represent a loss of \$17,815 in present discounted value of lifetime earnings (in 2006 USD) (Gould 2009).

24. Visual assessment of the adjusted associations between fluoride and intelligence confirmed the monotonic, mostly linear nature of the relationships (see Figures A and B). Notably, there was no evidence of a threshold among the 4-year olds, although there was some suggestion of a threshold at approximately 0.8 mg/L among the 6-12 year olds.

⁵ We have subsequently reported an analysis, in abstract form, of neurocognitive outcomes at ages 1 to 3, as measured through the Mental Development Index (Thomas 2018). These results are consistent with the age 4 and age 6-12 analyses in that they show significant adverse associations with maternal urinary fluoride. I do not rely on these results here, however, since they have not yet been published in full

Figure A: Visual Association Between Maternal Urinary Fluoride and Intelligence at Age 4

Figure B: Visual Association Between Maternal Urinary Fluoride and Intelligence at Ages 6-12

1 25. In contrast with prenatal exposures, we did not find statistically significant associations
2 between IQ and childhood urinary fluoride levels at ages 6 to 12, although there was some suggestion of
3 an adverse effect. This suggests that the timing of fluoride exposure is an important determinant of
4 fluoride's neurodevelopmental effects, and is consistent with exposures occurring prenatally being more
5 detrimental than those occurring during school-aged years. This is plausible given fluoride's passage
6 through the placental barrier, and the known enhanced vulnerability of the developing brain to
7 neurotoxins during the *in utero* period.

8
9 26. In addition to IQ, we have also found a significant association between prenatal fluoride
10 exposure and some attention deficit hyperactivity disorder (ADHD)-like behaviors on the CRS-R test,
11 including cognitive problems and inattention (Bashash 2018). As with our IQ analyses, the associations
12 were linear, although—as we have found for lead (Huang 2016)—there was some indication in some of
13 the analyses of a ceiling effect at higher doses (i.e., the dose-response curve for cognitive problems and
14 inattention began to flatten above 1 mg/L).

15
16 27. The effect sizes between prenatal fluoride and ADHD behaviors in our cohort were
17 substantial. For those effects which reached statistical significance, increases of 0.5 mg/L in maternal
18 urinary fluoride were associated with 2.4 to 2.8-point higher scores (higher scores reflect indicate poorer
19 performance). Whereas IQ is standardized to a mean of 100, the ADHD behavior scales are standardized
20 to a scale of 50. The effect sizes that we found for prenatal fluoride are similar to what we have found
21 for childhood blood lead levels (Huang 2016).

Figure C: Association Between Maternal Urinary Fluoride & ADHD Behaviors

28. We did not find statistically significant associations between fluoride and ADHD-behaviors on the CPT-II test. Other studies of environmental chemicals have reported similar discrepancies between the two tests, suggesting that they are assessing different constructs. The stronger association that we found between fluoride and ADHD behaviors on the CRS-R scale may be explained by the CRS-R's focus on constructs that rely on attention (e.g., new learning, ability to hold information and complete tasks, organizational skills, etc).

29. The relationship we observed between fluoride and inattention is consistent with some animal research that has reported a relationship between prenatal fluoride exposure and hypoactive behavioral patterns (Mullenix 1995), as well as prior epidemiological research associating fluoride with impaired working memory (Choi 2015). Working memory is linked with the ability to control attention and it is common for youth with ADHD to have weaknesses in working memory (Kasper 2012).

Fluoride's effect on working memory may relate to an effect on the dopamine system, which fluoride has been found to alter in animal studies (Pal & Sarkar 2014). Dopamine is an important modulatory neurotransmitter in planning and initiation of motor responses, activation, switching, reaction to novelty and processing of reward (Fararone 2015).

30. Some have suggested that the “scatter” in the above scatterplots is a basis to doubt the relation between fluoride and the neurodevelopmental outcomes. Such scatter, however, is typical in epidemiological studies of neurotoxicants, as can be seen in the following figure from our study on lead and neurocognitive effects which the EPA relied upon as evidence of low-level lead neurotoxicity when the Agency set the national air standard for lead (Tellez-Rojos 2006, Fig 1, reproduced as Figure D below). We also found similar scatter in our analysis of blood lead and ADHD behaviors, as measured by CRS-R (Huang 2016, Fig. 1, reproduced as Figure E below). The scatter relates to the fact that there are multiple factors that impact on intelligence and behavior; however, unless they are confounders (which we controlled for), they do not preclude the ability to focus on the specific effect of fluoride.

Figure D: Association Between Childhood Blood Lead Levels and Mental Development Index

Figure E: Association Between Childhood Blood Lead Levels and ADHD Behaviors

C. The Limitations of Our Studies Do Not Provide Plausible Alternative Explanations for the Results

31. Every epidemiological study, including our studies on fluoride and neurodevelopment, has its limitations. Some of these limitations could theoretically be avoided through the use of human experiments where the toxicant is delivered to the study participants in a controlled and randomized manner. Human experimentation on neurotoxicants, however, is strictly prohibited for obvious ethical reasons. We are thus left with “observational” studies to investigate the impact of environmental toxicants on human health, with prospective cohort studies being the study design best suited for this purpose.

32. As is often the case with epidemiological studies of environmental toxicants, there are limitations in the exposure measurements that we have used in the ELEMENT studies. Our use of spot samples to collect the urine introduces some imprecision into the exposure measurement because urinary

1 fluoride concentrations can fluctuate somewhat throughout the day. This imprecision would have been
2 reduced through the use of 24-hour urine collection samples, and, to a lesser extent, fasting first-morning
3 voids, which are both considered more rigorous measures of fluoride exposure. We compensated for this
4 limitation by using “timed” samples (i.e., second void in the morning) and adjusting for urinary
5 creatinine. Urinary fluoride concentrations fluctuate during the day in large part because fluctuations in
6 an individual’s hydration during the day result in fluctuations in urinary dilution (and therefore, urinary
7 concentrations). Adjusting for urinary creatinine is particularly important because the resulting measure
8 adjusts for urinary dilution. As a result, measures of fluoride in spot urine samples adjusted for
9 creatinine have been found to have excellent agreement with 24-hour samples (Zohouri 2006). Timed
10 spot samples also have an important advantage over 24-hour samples in that they are less imposing on
11 study participants. This is an important consideration when designing cohort studies because the
12 imposition of difficult tasks like collecting 24-hour urines serve to reduce participation, which, in turn,
13 reduces the study’s sample size and statistical power.⁶
14

15 33. Another limitation in our exposure measurements is that, for most of the mothers, we did
16 not have urine samples for every trimester. In our age 4 IQ analysis, 49%, 42%, and 9% of the mother-
17 offspring pairs had urine samples for one, two, and all three trimesters, respectively. In the age 6-12
18 analysis, the respective percentages were 56%, 39%, and 5%; while in the ADHD study, the respective
19 numbers were 57%, 36.4%, and 6.5%. It is common for prospective cohort studies to only have one or
20 two exposure measurements during the prenatal period, but this does not introduce undue imprecision in
21 the exposure estimate, as exposures to a toxicant have limited variation during pregnancy.
22

23 34. Importantly, the imprecision in our exposure measurements does not explain the large
24 and significant associations we observed between maternal urinary fluoride and neurodevelopmental
25

26 ⁶ To put it in simple terms, less people will volunteer to participate in a study if it requires them to
27 collect all of their urine throughout the entire day, including while they are in public spaces, such as
28 their work environment and restaurants, etc.

1 effects. Imprecision in exposure measurements (of the classical or random type, as noted above) is a
2 type of non-differential error that introduces scatter into the analysis which has a generally expected
3 effect of biasing the results towards the null hypothesis. To put it another way, imprecisions in exposure
4 measurements make it *harder*, not easier, to detect an association between an exposure and outcome,
5 much like background noise makes it harder to hear a sound or signal of interest. Imprecision in the
6 exposure measurement is thus anticipated to *obscure* an association, rather than create spurious
7 associations where none otherwise exist. Because of this, improvement in the measurement of a
8 particular exposure tends to reveal and strengthen associations associated with that exposure, not
9 eliminate them.
10

11 35. Another limitation with our studies is, as with most observational studies, we could not
12 rule out the potential for uncontrolled confounding from factors that we did not measure. For example,
13 we did not have data on arsenic which is a neurotoxicant that has been associated with fluoride in certain
14 rural drinking water supplies. While it is always preferable to have more data than less, it is unlikely that
15 arsenic is a meaningful confounder in our cohort. To be a confounder, a covariate must be associated
16 with *both* the outcome *and* exposure. In our cohort, the main source of fluoride is from *salt*, not water.⁷
17 Accordingly, even if arsenic is correlated with fluoride in rural water supplies in Mexico, this
18 association is unlikely to be materially associated with fluoride exposures in our cohort.
19

20 36. Finally, an additional limitation in our studies is that we did not have information on the
21 iodine status of our cohort. Iodine has been theorized to be a potential effect-modifier for fluoride's
22 nervous system effects, i.e., deficiencies of iodine may magnify fluoride's effects, and vice versa (NRC
23 2006). However, failure to control for an effect modifier is unlikely to produce an association between
24 exposure and outcome that does not otherwise exist. Moreover, in Mexico, salt is required by law to be
25

26 ⁷ The water in Mexico City has low levels of fluoride (i.e., 0.16 mg/L) and thus does not present a
27 meaningful exposure in our cohort (Cantoral et al. 2019).

1 iodized. Fluoride levels in our cohort are thus likely correlated with *increased* iodine. To the extent that
2 iodine modifies the effect of fluoride in our population, it is more likely to be in the direction of
3 *reducing* toxicity rather than magnifying it.

4 **D. Implications of Our Findings to the General Population in Water-Fluoridated**
5 **Areas**

6 37. In 2016, we published the largest characterization to date of urinary and plasma fluoride
7 levels throughout pregnancy (Thomas, et al. 2016). At the time we published this study, there had yet to
8 be a population-based study of fluoride exposures among pregnant women in North America, although
9 there were two small-scale studies available from Israel and Poland. The lack of data from North
10 America prevented us, at that time, from comparing the urinary fluoride levels in our cohort with
11 populations from Canada or the United States.

12 38. Urine and plasma fluoride are metrics of the total absorbed dose of fluoride, sometimes
13 referred to as the “internalized” or “bioavailable” dose. These internalized doses do not currently permit
14 one to directly estimate the amount of fluoride that is ingested (i.e., the “external” exposure), nor do they
15 permit the determination of source apportionment of the fluoride exposures. Internalized doses,
16 however, are more relevant than external intake in predicting toxic effects, since they reflect the
17 concentration of toxics that are being delivered to target organs in the body.

18 39. Our 2016 study presented the urinary and plasma fluoride levels from 825 and 330
19 pregnant women from our cohort, respectively. The urine samples were collected and measured using
20 the procedures discussed above for our neurodevelopmental papers (i.e., early morning 2nd voids that
21 were adjusted for creatinine), and both the urine and plasma samples were tested under the direction of
22 Dr. Angeles Martinez-Mier from Indiana University, a world leader in the measurement of fluoride in
23 biological samples.

24 40. The average creatinine-adjusted urinary fluoride level across all three trimesters in the
25
26
27
28

1 ELEMENT cohort was 0.91 mg/L, with a standard deviation of 0.4 mg/L.⁸ The average plasma fluoride
2 level across all three trimesters was 0.0221 mg/L, with a standard deviation of 0.0164 mg/L.⁹

3 41. By the time we published our 2018 study on ADHD behaviors, general population data
4 had become available on maternal urinary fluoride levels in pregnancy (Till 2018). As we noted in our
5 2018 study, the maternal fluoride levels in the Canadian study are similar to the levels in our cohort
6 (Bashash 2018). The mean (creatinine-adjusted) maternal urinary fluoride level among pregnant women
7 living in the water-fluoridated areas of Canada was 0.87 mg/L, with a standard deviation of 0.50 mg/L,
8 which is clearly in the same range as our cohort (i.e., mean = 0.91 mg/L, SD = 0.4 mg/L). The urine
9 samples in the Canadian study were tested by Dr. Martinez-Mier using the same creatinine-adjustment
10 method, which increases the comparability of the data.
11

12 42. The similarity in maternal urinary fluoride levels between pregnant women in the
13 ELEMENT cohort and water-fluoridated areas of the Canadian cohort is consistent with the fact that
14 both populations are receiving so-called “optimal” levels of fluoride through fluoridation programs (i.e.,
15 salt fluoridation in Mexico, and water fluoridation in Canada). Since salt fluoridation programs are
16 designed to replicate the doses provided by fluoridated water, it is a reasonable, first-order expectation
17 that populations living in salt-fluoridated and water-fluoridated areas will receive similar doses of
18 fluoride.
19

20 43. The maternal urinary fluoride data from the ELEMENT cohort and water-fluoridated
21 areas of Canada support the conclusions that the two populations have essentially the same *internalized*
22 doses of fluoride. The internalized doses in water-fluoridated areas are thus in the range that we have
23

24 ⁸ The 75th and 90th percentile values were 1.09 mg/L and 1.37 mg/L, respectively.

25 ⁹ We tested for and found no correlation between creatinine-adjusted urinary fluoride and
26 sociodemographic variables, including maternal age, maternal education, child sex, smoking status, birth
27 order, and cohort. Although we found a trend towards increasing urinary fluoride levels through the first
28 22-23 weeks of pregnancy, and a reduction thereafter, these trends were not statistically significant
(Thomas 2016).

1 found to be associated with substantial and significant neurodevelopmental harms in the ELEMENT
2 cohort.

3 44. Although direct comparisons of *external* fluoride intake cannot yet be made, such
4 information is not necessary to generalize the neurodevelopmental results from the ELEMENT cohort to
5 water-fluoridated areas.

6 45. There is no identified reason to believe that the neurodevelopmental effects of fluoride
7 will differ by the source of exposure, be it fluoridated salt or fluoridated water; once inside the body the
8 source of fluoride is immaterial.

9 46. For the reasons stated, it is my opinion to a reasonable degree of scientific certainty that
10 the results of the ELEMENT studies support the conclusion that fluoride is a developmental
11 neurotoxicant at levels of internalized exposure seen in water-fluoridated communities.
12

13
14 I declare under penalty of perjury, under the laws of the United States, that the foregoing
15 is true and correct to the best of my knowledge and belief.
16

17 Executed on May 20, 2020, in Seattle Washington.

EDUCATION:

9/1973-6/1976	Biology	B.Sc.	Brown University
9/1977-6/1982	Medicine	M.D.	Albert Einstein College of Medicine
9/1979-6/1980 (degree in 6/1982*)		M.P.H. (Occ Hlth)	Harvard School of Public Health
9/1985-6/1986	Epidemiology	M.S.	Harvard School of Public Health
7/1986-6/1990	Epidemiology	Sc.D.	Harvard School of Public Health

* Awarding of the Harvard M.P.H. to medical students is delayed until the M.D. degree is conferred

POSTDOCTORAL TRAINING:

Research Fellowships

7/1987-6/1988 Occupational Health Research Fellow, Dept. of Environmental Health
Harvard School of Public Health

Internship and Residencies

7/1982-6/1983	Intern in Medicine	Boston City Hospital
7/1983-6/1984	Junior Assistant Resident, Internal Medicine	Boston City Hospital
7/1984-6/1985	Senior Assistant Resident, Internal Medicine	Boston City Hospital
7/1985-6/1987	Resident, Occupational Medicine	Harvard School of Public Health

CERTIFICATION AND LICENSURE:

1984	Massachusetts Medical License Registration
1985	American Board of Internal Medicine, Diplomate
1987	American Board of Preventive Medicine, Diplomate (Occupational Medicine)
2006	Michigan Medical License Registration
2013	College of Physicians & Surgeons of Ontario
2018	Washington State Medical License Registration

ACADEMIC APPOINTMENTS:

9/1988-6/1992	Instructor in Medicine Department of Medicine, Harvard Medical School
9/1988-6/2006	Associate Physician (Clinical and Research), Channing Laboratory, Department of Medicine, Brigham & Women's Hospital
9/1990-6/1994	Assistant Professor of Occupational Medicine Department of Environmental Health, Harvard School of Public Health

CV: Howard Hu, M.D., M.P.H., Sc.D.

7/1992-6/1997 Assistant Professor of Medicine
Department of Medicine, Harvard Medical School

7/1994-6/2002 Associate Professor of Occupational Medicine
Department of Environmental Health, Harvard School of Public Health

7/1997-8/2006 Associate Professor of Medicine
Department of Medicine, Harvard Medical School

7/2002-8/2006 Professor of Occupational and Environmental Medicine (tenured)
Department of Environmental Health, Harvard School of Public Health

9/2006-6/2012 Chair and Professor of Environmental Health Sciences (tenured), Department of
Environmental Health Sciences, University of Michigan School of Public Health

9/2006-8/2009 Adjunct Professor of Occupational and Environmental Medicine
Department of Environmental Health, Harvard School of Public Health

9/2006-6/2012 Research Associate Physician, Channing Laboratory, Department of
Medicine, Brigham & Women's Hospital

5/2007-2012 Professor of Epidemiology, University of Michigan School of Public Health

5/2007-2012 Professor of Internal Medicine, University of Michigan Medical School

1/2009-2012 NSF International Endowed Department Chair, University of Michigan School of
Public Health, Department of Environmental Health Sciences

7/2012-2018 Professor of Environmental Health, Epidemiology and Global Health (tenured)
Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario,
Canada (on sabbatical/administrative leave, 2017-2018)

7/2012-2018 Professor, School of Medicine, University of Toronto, Toronto, Ontario, Canada

7/2012- Adjunct Professor, Department of Environmental Health Sciences, University of
Michigan School of Public Health

7/2012-2013 Director, Dalla Lana School of Public Health, University of Toronto, Toronto,
Ontario, Canada

7/2013-6/2017 Founding Dean, Dalla Lana School of Public Health, a Faculty of the University
of Toronto, Toronto, Ontario, Canada

7/2017- Affiliate Professor (started as Visiting Scholar until December, 2017),
Department of Occupational and Environmental Health Sciences, University of
Washington School of Public Health, Seattle, WA

ADMINISTRATIVE APPOINTMENTS:

7/1991-6/2006 (Founding) Director, Metals Epidemiology Research Group, Channing Laboratory,
Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, and
Department of Environmental Health, Harvard School of Public Health

7/1992-6/1995 Director, Commission to Investigate the Health and Environmental Effects of Nuclear
Weapons Production, International Physicians for the Prevention of Nuclear War

7/1996-6/2006 Director, Residency Program in Occupational and Environmental Medicine, Harvard
School of Public Health

7/1996-8/2006 Director, Occupational and Environmental Medicine Core, National Institute for
Occupational Safety and Health Educational Resource Center at the Harvard School of

CV: Howard Hu, M.D., M.P.H., Sc.D.

Public Health

- 7/1998-6/2004 (Founding) Medical Editor, Environmental Health Perspectives (official journal of NIEHS)
- 7/2000-8/2006 Associate Director, the Harvard NIEHS Environmental Sciences Center, Harvard School of Public Health
- 7/2004-6/2009 (Founding) Principal Investigator and Director, Harvard Center for Children's Environmental Health and Disease Prevention Research (co-PI and co-Director after 9/1/08)
- 9/2006-6/2012 Chair, Department of Environmental Health Sciences, University of Michigan School of Public Health
- 9/2006-2012 Director, Occupational Epidemiology Core, NIOSH Education and Research Center, University of Michigan
- 9/2006-2012 Co-Director, Michigan-Harvard/Harvard-Michigan Metals Epidemiology Research Group
- 7/2009-2011 Director, NIA T32 Training Grant in Aging and Public Health, University of Michigan School of Public Health
- 1/2010-2012 Chair, Faculty Steering Committee on Global Health, University of Michigan School of Public Health
- 4/2011-2012 (Founding PI) and Director, University of Michigan NIEHS P30 Core Center.
- 7/2012-2013 Director, Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada
- 7/2013-6/2017 Founding Dean, Dalla Lana School of Public Health, a Faculty of the University of Toronto, Toronto, Ontario, Canada

CLINICAL APPOINTMENTS:

- 7/1985-6/1987 Attending Physician, Emergency Department, Whidden Memorial Hospital
- 7/1985-6/1988 Assistant Visiting Physician, Department of Medicine, Boston City Hospital
- 1/1985-6/2006 Consultant in Occupational and Environmental Medicine, Center for Occupational and Environmental Medicine, Northeast Specialty Hospital (formerly known as the Olympus Specialty Hospital, the Massachusetts Respiratory Hospital, and Norfolk County Hospital).
- 3/1987-9/1987 Attending Physician, Occupational Health Program, University Hospital/Boston University Medical Center
- 7/1988-9/2006 Associate Physician, Brigham and Women's Hospital
- 7/1990-6/1995 Occupational/Environmental Medicine Consultant, Brigham and Women's Hospital Employee Health Services
- 7/2007-2012 Associate Physician, Division of General Medicine, Department of Medicine, University of Michigan Health System
- 1/2019-present Staff Physician, RotaClinic-Lake City, Seattle, WA

OTHER ACADEMIC POSITIONS and MAJOR VISITING APPOINTMENTS:

CV: Howard Hu, M.D., M.P.H., Sc.D.

7/1987-6/1990 Visiting Physician, South Cove Health Center, Boston (Chinatown)
 7/1996-8/2006 Associate, Center for Health and the Global Environment, Harvard Medical School
 2/1997 Alice Hamilton Visiting Professor, Division of Occupational and Environmental
 Medicine, Department of Medicine, University of California at San Francisco
 11/2000- Visiting Scientist, Sri Ramachandra Medical College and Research Institute
 7/2010- Senior Consultant, Tianjin Centers for Disease Control and Prevention, Tianjin,
 China
 10/2012- Visiting Professor, Shanghai Key Laboratory of Children's Environmental Health,
 Xinhua Hospital, Shanghai Jiao-Tung University, China
 7/2013-6/2016 Visiting Professor, Shanghai Jiao Tong School of Medicine, China
 5/2015- Affiliate Scientist to the Li Ka Shing Knowledge Institute, St. Michael's Hospital,
 Toronto, Canada

MAJOR RESEARCH INTERESTS:

1. Environmental and molecular epidemiologic research related to heavy metals, potential endocrine disruptors, other neurotoxicants, carcinogens, etc.
2. Gene-environment interactions; epigenetic dysregulation
3. Fetal/early life exposures and long-term effects
4. Aging-environment interactions
5. Environmental health, health inequities and health disparities, human rights
6. Health and the global environment
7. "Big Data" for population health
8. Environmental sensitivities/Multiple chemical sensitivities

GRANTS (as PI, Co-PI, or primary mentor only):

Past Funding:

1980 (summer) Montefiore Hospital, Bronx NY, PI; \$2,000 (approx)
 A study of rural and occupational health in Tulua, Colombia, South America
 1982 (summer) Albert Einstein College of Medicine, PI; \$3,000 (approx)
 A study of occupational/environmental health in Shanghai, China
 7/1987-6/1989 NIEHS Center Grant ES00002 Pilot Project, PI; \$12,000
 The Long-term Renal and Neurologic Effects of Childhood Plumbism
 7/1989-6/1990 NIEHS subcontract 7083-1, PI; \$50,000 (approx)
 The Use of X-Ray Fluorescence to Measure Lead Burden and Childhood Lead
 Exposure
 7/1990-6/1992 Agency for Toxic Substances and Disease Registry, PI; \$150,000 (approx)
 "Clinical Environmental/ Occupational Medicine Research Fellowship Award",
 7/1990-6/1991 NIEHS Center Grant ES00002 Pilot Project, PI; \$12,000
 The Metabolic Effects of Pregnancy and Lactation on Lead Burden

CV: Howard Hu, M.D., M.P.H., Sc.D.

7/1990-6/1991 Harvard School of Public Health Basic, PI
Research Support Grant; \$10,000
K-X-Ray Fluorescence Measured Lead Burden

10/1991-11/1991 NIOSH Special Grants, PI; \$50,000 (approx)
The Carpenters Lead Project

4/1991-3/1996 NIEHS/R01, PI; \$2,200,000 (approx)
The Epidemiology of Lead, Diet and Blood Pressure

7/1991-6/1996 NIEHS/R01 supplement, PI; \$240,000 (approx)
The Epidemiology of Lead, Diet and Blood
Pressure--Research Supplement for Minority Investigator

7/1992-6/1995 NIEHS/R01 (Office of Research on Women), PI; \$200,000 (approx)
Lead and Hypertension in Women

7/1993-6/1996 NIEHS/subcontract, PI; \$150,000 (approx)
Exposure to Neurotoxins as Risk Factors for Amyotrophic Lateral Sclerosis

7/1995-6/1998 State of Washington, Department of Labor, PI; \$350,000 (approx)
SPECT Imaging of the Brain in Patients with Multiple Chemical Sensitivity
Syndrome and Controls

7/1996-6/1997 NIEHS Center Grant ES00002 Pilot Project, PI; \$15,000
Electrocardiographic abnormalities in association with low-level lead exposure
among middle-aged to elderly men: the Normative Aging Study

4/1995-3/2000 NIEHS Project PI (Program Project PI: Richard Monson); \$1,800,000 (approx)
Lead Exposure, Accumulation in Bone, and Reproductive Toxicity Among Men and
Women In Mexico

4/1995-3/2000 NIEHS Project PI (Program Project PI: Richard Monson); \$1,900,000 (approx)
Lead Exposure, Accumulation in Bone, and Cognitive Toxicity Among Elderly Men
and Women

6/1997-5/2002 NIEHS/R01 ES05257 PI; \$2,312,274
Lead Biomarkers, Aging, and Chronic Disease

7/1997-6/1999 NIEHS Center Grant ES00002 Pilot Project, PI; \$10,000
The effect of genetic polymorphisms of metallothionein-IIA on mRNA levels in
middle-aged to elderly men: the Normative Aging Study

7/1998-6/2003 NIEHS/R01 PI (with no-cost extension; 5R01ES007821); \$2,291,833
Lead Dose Biomarkers, Reproduction, and Infant Outcomes

7/1999-6/2000 NIEHS Center Grant ES00002 Pilot Project, co-PI; \$14,000
Magnetic Resonance Spectroscopy in the Evaluation of Lead Neurotoxicity: the
Normative Aging Study

7/2000-6/2001 MAVERIC (Massachusetts Area Veterans Epidemiology Resource and Institute
Center) Pilot Project PI (with Dr. Robert Wright, co-PI); \$10,000
The Use of Magnetic Resonance Spectroscopy in Lead Poisoning

7/2000-6/2001 NIOSH Center Grant Pilot Project, PI (with Dr. Robert Wright, co-PI); \$12,000
Interaction between ApoE Genotype and Lead Exposure in the Development of
Cognitive Impairment

7/2002-6/2004 The Rasmussen Foundation/Health Care Without Harm; \$50,000

- Year Award", 1998-1999
- 1999 True Memorial Lecturer, Maine Medical Center, Portland ME.
- 2000-2001 Faculty Sabbatical Award, Harvard School of Public Health
- 2000-2001 Senior Fulbright Scholar in India
- 2001 Hoopes Prize, Faculty Mentorship (for Senior Thesis of Charles Lin, "More than Black and White: Lead Poisoning as an Environmental Justice Issue in Boston")
- 2003 Best Paper in Preventive Medicine by a Medical Student (for Senior Thesis of Vanitha Janakiraman; Janakiraman V, Hu H, Mercado-Garcia A, Hernandez-Avila M. A randomized crossover trial of nocturnal calcium supplements to suppress bone resorption during pregnancy. *Am J Prev Med* 2003;24:260-4.). American College of Preventive Medicine, Ulrich and Ruth Frank Foundation for International Health.
- 2004 Das Travel Grant Award, The South Asia Initiative, Harvard University (for Travel in India)
- 2005 Adolph G. Kammer Merit in Authorship Award, the American College of Occupational and Environmental Medicine (for Rhodes D, Spiro A, Aro A, Hu H "Relationship of Bone and Blood Lead Levels to Psychiatric Symptoms: The Normative Aging Study", Published in the *Journal of Occupational and Environmental Medicine*)
- 2006 Teacher of the Year Award, Occupational/Environmental Medicine Residents, Harvard School of Public Health
- 2006 Harriett Hardy Award, the New England College of Occupational and Environmental Medicine
- 2009 Linus Pauling Award for Lifetime Achievements, American College for the Advancement of Medicine
- 2011 Award for Excellence, American Public Health Association
- 2015 John R. Goldsmith Award for Outstanding Contributions to Environmental Epidemiology, International Society for Environmental Epidemiology
- 2016 Election to Fellowship, Canadian Academy of Health Sciences

TEACHING:

1. LOCAL CONTRIBUTIONS (at the Harvard School of Public Health, 1985-2006)

1985-	“Toxicology of the Kidney and Urinary Tract” Guest Lecturer for TOX204a,b
1988-	“Occupational Health” Guest Lecturer for EH201a,b
1989-1992	“Lead Toxicology” Guest Lecturer for TOX204a,b
1990-	<u>Grand Rounds in Occupational/Environmental Medicine</u> Director
1990-2000	<u>Introduction to Occupational and Environmental Medicine (EH232c,d)</u> Course director, lecturer
1990-	“The Epidemiology of Lead Exposure, Dose, and Toxicity” Guest Lecturer for EPE215c,d and EPE215t
1990-	“Solvent toxicity” Fundamentals of Industrial Hygiene, Continuing Education Department
1992	"Current Research on Lead", Metals Epidemiology Research Group Seminar Presenter
1992	"Lead Poisoning Without a Known Source in a Hyperthyroid Patient" Case discussant, Grand Rounds in Occupational and Environmental Medicine
1992-	“Biological Markers of Lead Dose” Guest Lecturer, EHE280c,d
1994-	“Screening for Lead Toxicity” Guest lecturer, EPI227d
1994-	“Lead Exposure and Biological Monitoring” Guest Lecturer, ID263b
1994-	“Case Study: Lead” Guest Lecturer and Case Discussant, EH202d
1996-	<u>Introduction to Environmental Health (EH201b)</u>

CV: Howard Hu, M.D., M.P.H., Sc.D.

CV: Howard Hu

13

- 1997- Course director and lecturer
Human Health and Global Environment Change (EH278a,b)
 Course Co-developer, Co-director, and lecturer

Hospital courses and Invited Teaching Presentations (Harvard-affiliated Hospitals)

- 1990 Guest Lecturer on Occupational Medicine
 Residency Program, Department of Medicine, Brigham and Women's Hospital
- 1994 Speaker, Grand Rounds; "Is Lead a Ticking Time Bomb?"
 Department of Obstetrics and Gynecology, Brigham and Women's Hospital
- 1994 Speaker, Grand Rounds; "Is Lead a Ticking Time Bomb?"
 Department of Medicine, Brockton V.A. Hospital
- 1994 Speaker, Symposium on Preventive Medicine and Clinical Epidemiology,; "Is Lead a Ticking Time Bomb"; Brigham and Women's Hospital
- 1995 Discussant, "Multiple Chemical Sensitivity", Occupational/Environmental Medicine
 Grand Rounds, Occupational Health Program, Harvard School of Public Health
- 1996 Guest lecturer, "Lead Toxicity as a Paradigm for a Regional and Global Health Hazard", Environmental Health Student Group, Holmes Society, Harvard Medical School
- 1997 Speaker, "Mobilization of maternal bone lead as a hazard to the fetus", Grand Rounds, Dept. of Neonatology, Beth Israel Hospital, Boston, MA
- 2000 Guest lecturer, "Update on Lead Toxicity Research", Program in Pediatric Toxicology, Children's Hospital
- 2000 Discussant, "Adult Lead Toxicity", Weekly Case Round, Department of Medicine, Brigham and Women's Hospital, Boston.
- 2000 Lecturer, "Update on Lead Toxicity, Hypertension, and Chronic Renal Failure", Renal Rounds, Division of Nephrology, Department of Medicine, Brigham and Women's Hospital, Boston.
- 2002 Lecturer, "Maternal Bone Lead as a Threat to Fetal Development", Program in Neonatology, Beth Israel-Deaconness Hospital, Boston, MA

Post-doctoral fellow mentor:

Dr. Marinelle Payton (Channing Lab), Dr. Susan Korrick (Channing Lab), Dr. Rokho Kim (Channing Lab), Dr. Viji Potula (HSPH Research Fellow), Dr. Barbara Nowak (Visiting Scientist from Silesian University School of Medicine, Poland), Dr. Robert Wright (Channing Lab), Dr. Ming Tsuang Wu (HSPH Research Fellow), Dr. Yawen Cheng (Channing Lab), Dr. Geeta Mathur (neonatology fellow at the Brigham and Women's Hospital), Dr. Sri Hari Bojja (HSPH Research Fellow), Dr. Hae-Kwan Cheong (Visiting Scientist from Dongguk University School of Medicine, S. Korea), Dr. Sahar Elmarsafawy (HSPH Research Fellow), Dr. Jing Lu (Visiting Scientist from the Chinese Academy of Preventive Medicine), Dr. Dieter Affeln (Occ/Env Med Fellow), Dr. Ahmed Gomaa (Occ/Env Med Fellow), Dr. Chris Leffler (Occ/Env Med Fellow), Dr. Ronald Dykeman (Occ/Env Med Fellow), Dr. Uma Dhanabalan (Occ/Env Med Fellow), Dr. Hsien-Wen Hsu (Occ/Env Med Fellow), Dr. Betty Ann Cohen (Occ/Env Med Fellow), Dr. Arvin Chin (Occ/Env Med Fellow), Dr. Daniel Rhodes (Occ/Env Med Fellow), Dr. Richard Wittman (Occ/Env Med Fellow), Dr. Sun-Dong Lee (Visiting Scientist from Sangji University, Korea), Dr. Ronald Green (Occ/Env Med Fellow), Dr. Erma Lawson (Environmental Health Fellow), Dr. Marc Weisskopf (Environmental Health Fellow), Dr. Bridget Bagert (Occ/Env Med Fellow), Dr. John Jarrell (Visiting Scientist from University of Calgary), Dr. Jennifer Weuve (Environmental Health Fellow), Dr. Karen Chou (Visiting Scientist from Michigan State), Dr. Nitin Jain (Channing Laboratory Fellow), Dr. Adrienne Ettinger (Children's Center Scientist), Dr. Sam Myers (Fellow in Alternative and Complementary Medicine), Dr. Marcelo Targino (Occ/Env Med Fellow), Dr. Manish Arora (Post-doctoral fellow from University of Sydney), Dr. Huiling Nie (Post-doctoral fellow from McMaster University).

Other faculty mentorship:

Elizabeth Rubinstein (HMS Summer research), Alicia Marier (HMS Summer research), Vanitha Janakiraman (HMS Summer research), Young-Sook Lim (Harvard College Summer research), Charles Lin (Harvard College Senior thesis research), Ed Hsieh (Harvard College Summer research), Naveen Thomas (Emory University Medical School Senior thesis research), Shreekrishna Akilesh (Harvard Dental School summer research), Christine Pace (HMS Summer research)

Advisory and supervisory responsibilities

1985-1987 Attending Physician, outpatient general medicine clinic, Boston City Hospital; weekly precepting for housestaff and medical students

CV: Howard Hu, M.D., M.P.H., Sc.D.

CV: Howard Hu

15

- 1990-2006 Preceptor, Residency in Occupational and Environmental Medicine, Harvard School of Public Health at the Mass Respiratory Hospital
- 1990-2006 Advisor to general M.P.H. students, Harvard School of Public Health.

2. LOCAL CONTRIBUTIONS (at the University of Michigan, 2006-2012)

- 2006- Principles of Environmental Health (EHS-500)
Course director and lecturer
- 2006- Environmental Epidemiology (EHS-608)
Guest lecturer on birth cohorts and environmental epidemiology
- 2006- Occupational and Environmental Disease (EHS-501)
Guest lecturer on metals exposure and health effects; Course Director (2009-)
- 2007- Metals Exposure, Biomarkers and Toxicity: A Multi-disciplinary Environmental Epidemiology Approach (EHS-698 reading course)
Course director and lecturer
- 2008-2009, Topics in Environmental Health Sciences (EHS-688)
2010-2011 Course director and lecturer
- 2009 Occupational and Environmental Disease (EHS-501)
Course director and lecturer
- 2009- On-line (Long-distance Foundations in Public Health Certificate Program): Principles of Environmental Health (EHS-500-801)
Course director and lecturer
- 2009 Introduction to Public Health (HMP-200)
Guest lecturer on environmental health
- 2009- Seminars in Aging and Public Health (EPID 813)
Course director and lecturer
- 2011 Seminar on Public Health in China (HMP-xxx)
Guest lecturer on "Environmental Health in China"

Post-doctoral fellow mentor:

Dr. Sung Kyun Park (Environmental Health Sciences Fellow, now Research Assistant Professor), Dr. Brisa Sanchez (Biostatistics Research Assistant Professor, now Assistant Professor), Dr. Richard Pilsner (Robert Wood Johnson Health & Society Fellow), Dr. Aimin Zhang (Environmental Health Sciences Fellow, Toxicology Training Grant), Dr. Ananya Roy (Environmental Health Sciences Fellow), Dr. David Cantonwine (Reproductive Sciences Fellow).

- 2009 Reviewer, NIH Challenge Grants, Special Emphasis Panel/Scientific Review Group
2009/10 ZRG1 GGG-F
- 2009-2010 External Member, Academic Program Review Site Visit Committee, Department of Environmental and Occupational Health Sciences, University of Washington School of Public Health
- 2010-2012 Member, External Advisory Committee, University of Rochester NIEHS P30 Core Center
- 2010 Member, Ad-hoc review committee, National Health Research Institutes of Taiwan, Special Emphasis Panel—NHRI-Kaoshiung Medical College Program Project on “: “Gene Environment Interaction in the Genesis of Asthma and Allergic Diseases”
- 2010-2012 Member, Advisory Board, Institute of Public Health, Florida Agricultural & Mechanical University, Tallahassee, FL
- 2011 Reviewer, NIEHS Career Development Awards, Special Emphasis Panel/Scientific Review Group 2011/05 ZES1 LKB-J (K9)
- 2011-2016 Member, NIEHS National Advisory Environmental Health Sciences Council
- 2012 Member, Editorial Board, Journal of Alzheimer’s Disease
- 2015 Member and External Reviewer, School of Population and Public Health Review Committee, University of British Columbia, Vancouver, B.C.
- 2016- Chair, Board of Directors, Canadian Urban Environmental Health Research Consortium, (National Consortium based out of the Dalla Lana School of Public Health)
- 2017- Member, Energy Research Committee, Health Effects Institute, Boston, MA
- 2017-2018 Executive Co-Chair, Workshop on the Global Burden of Disease-Pollution and Health Initiative, March 1-2, 2018, Institute for Health Metrics and Evaluation, Seattle, WA
- 2017- Executive Co-Leader, Global Burden of Disease-Pollution and Health Initiative
- 2019- Member, Research Advisory Committee, Centre of Environmental Health, The Public Health Foundation of India and the Tata Institute of Social Sciences, New Delhi, India
- 2019- Reviewer, draft report on trace metals levels in pregnancy women, Agency for Toxic Substances and Disease Registry, Centers for Disease Control and Prevention, Atlanta

Regional

- 1988-1990 Health Facilities Appeals Board, Member, Dept. Public Health, Comm. Of Mass.
- 1988-2006 Advisory Board, Massachusetts Department of Public Health, Sentinel Event Notification System for Occupational Risks (SENSOR) Project
- 1989-1995 Advisory Board, Massachusetts Division of Occupational Hygiene, Lead Registry Project
- 1990-1992 Board of Directors, Member, Health Care for All, Boston, Massachusetts
- 1993-1995 Faculty Council, Member, Harvard School of Public Health
- 1995-2006 Faculty Advisory Committee, Public Health Practice Program, Harvard School of Public Health

CV: Howard Hu, M.D., M.P.H., Sc.D.

1996-2006 Advisory Board, Boston VA Environmental Hazards Center, Boston

1997-2001 Faculty Steering Committee, Center for Children's Health, Harvard School of Public Health

1996-2006 Senior Epidemiology Consultant, Massachusetts Veterans Epidemiology Research and Information Center, Boston.

1996-2006 Associate, Center for Health and the Global Environment, Harvard Medical School

1997-2002 Faculty Advisory Committee on Continuing Professional Education, Harvard School of Public Health

1998-2006 Faculty Steering Committee, Masters of Public Health program, Harvard School of Public Health

2001-2003 Board of Directors, New England College of Occupational and Environmental Medicine

2001-2006 Associate Director, Harvard NIEHS Environmental Sciences Center, Harvard School of Public Health

2001-2006 Senior Advisory Council Member, Lowell Center for Sustainable Production, University of Massachusetts, Lowell, MA

2003-2006 Member, Human Subjects Committee, Harvard School of Public Health

2003-2006 Advisory Committee, Occupational Health Services Research Program, Harvard School of Public Health

2006 Study Section Review Committee, Pilot Project Program, Graham Environmental Sustainability Institute, School of Natural Resources and Environment, University of Michigan

2006-2007 Chair, Planning Committee, Health Sector, May 8-10, 2007 National Summit on Coping with Climate Change, University of Michigan

2007-2009 Member, Advisory Committee, SPH Practice Committee, University of Michigan School of Public Health

2007-2012 Member, Residency Advisory Committee, General Preventive Medicine Residency, University of Michigan School of Public Health

2008-2009 Member, Steering Committee, NIA T32 Training Grant on Aging Research (PI: Mary Haan), University of Michigan School of Public Health

2008-2013 Member, Advisory Committee, Outstanding New Environmental Scientist Awardee (Marie O'Neill), NIEHS

2008-2009 Member, Search Committee for Director of the Risk Science Center, University of Michigan School of Public Health

2009 Co-Chair, Planning Committee, Workshop on Predicting and Preventing Climate Change Impacts on Public Health, Goa, India (Collaboration with the UM Center for Global Health, the US Centers for Disease Control and Prevention, and the Indian Council for Medical Research)

2009-2011 Director and PI, NIA T32 Training Grant on Aging Research, University of Michigan School of Public Health

2009-2010 Member, Planning Committee, University Research Corridor (U of M, Michigan State, Wayne State) symposium on environmental health sciences in January 2010

2009-2012 Faculty Associate, Center for Global Health, University of Michigan
 2009-2012 Member, Internal Advisory Board, Cancer Epidemiology Education in Special Populations Program, University of Michigan School of Public Health
 2009-2011 Chair, Steering Committee on Global Health, University of Michigan School of Public Health
 2010-2012 Member, Executive Committee, Graham Environmental Sustainability Institute, University Of Michigan
 2010-2012 Member, Committee on Diversity, University of Michigan School of Public Health
 2012-2017 Chair, Executive Committee, Dalla Lana School of Public Health, University of Toronto
 2012-2017 Chair, Tenure Committee, Dalla Lana School of Public Health, University of Toronto
 2012-2017 Chair, Decanal Promotions Committee, Dalla Lana School of Public Health, University of Toronto
 2012-2017 Chair, Executive Advisory Committee, Institute for Global Health Equity & Innovation, Dalla Lana School of Public Health, University of Toronto
 2013-2015 Interim Director, Institute for Global Health Equity & Innovation, Dalla Lana School of Public Health, University of Toronto
 2013-2014 Co-Chair, Research Committee, Dalla Lana School of Public Health, University of Toronto
 2014-2017 Chair, Executive Advisory Committee, Institute for Health Policy Management and Evaluation, University of Toronto
 2014 Chair, Ad-hoc Committee to create an Institute for Indigenous Health (based on a \$10 million endowment gift made to DLSPH), Dalla Lana School of Public Health, University of Toronto; Chair, Executive Advisory Committee beginning 2015
 2015-2017 Chair, Executive Advisory Committee, Joint Centre for Bioethics, University of Toronto
 2015- Chair (2015-2017); Member (2017-present), Taskforce on Environmental Health, Ministry of Health and Longterm Care, Province of Ontario
 2016-2017 Chair, Executive Advisory Committee, Centre for Critical Qualitative Health Research, University of Toronto
 2017-2018 Executive Co-Chair, Workshop on the Global Burden of Disease-Pollution and Health Initiative (a collaboration between the Global Alliance on Health and Pollution and the Institute for Health Metrics), Seattle, WA

Hospital

1982-1985 Occupational Safety and Health Committee, Member, Boston City Hospital, Boston
 1983-1984 House Officers Association, Treasurer, Boston City Hospital
 1984-1985 House Officers Association, Co-President, Boston City Hospital

OTHER PUBLIC SERVICE

1987 Member, Fact-finding tour on "The Health Effects of Massive Exposure to Tear Gas",

CV: Howard Hu, M.D., M.P.H., Sc.D.

CV: Howard Hu

23

- Seoul, South Korea, July 11-18 (Sponsored by Physicians for Human Rights, American College of Physicians)
- 1988 Member, Fact-finding tour on "Chemical Weapons and the Iraqi Kurdish refugees", Turkey Oct 6-16 (Sponsored by Physician for Human Rights and the MacArthur Foundation)
- 1990 Leader, Fact-finding tour on "Health and Human Rights in Burma (Myanmar)", Thailand-Burma Dec. 26-Jan 6 (Sponsored by Physician for Human Rights and the MacArthur Foundation)
- 2009 Consultant and senior advisor, Fact-finding tour on "Mining and Potential Exposures and Health Effects in Guatemala", August 2009 (Sponsored by Physicians for Human Rights)

CONSULTING POSITIONS

- 1987-1989 Consultant, "In-Vivo Total Body Lead Analysis by X-Ray Fluorescence", NIH/SBIR Grant 2R44ES03918-02
- 1988-1989 Consultant, "Boston Area Health Coalition Demonstration Project", DHHS/MP000003-A1
- 1993-1995 Consultant, Employee Health Services, Brigham and Women's Hospital
- 1994 Consultant, Public Welfare Foundation, Washington, DC (review of Environmental Programs)
- 1997-2006 Consultant, Pediatric Environmental Health Center, Children's Hospital, Boston, MA
- 2000 Consultant, Doris Duke Foundation, New York, NY (review of potential Environment and Medicine programs)
- 2009-2010 Consultant and Member, Academic Program Review Site Visit Committee, Department of Environmental and Occupational Health Sciences, University of Washington School of Public Health, Seattle, WA
- 2011 Consultant, JPB Foundation, New York, NY (review of Environmental Health programs)
- 2014- Advisor, Hearing Health Sciences, Ann Arbor MI and Amsterdam, Netherlands

VISITING PROFESSORSHIPS

- 1997 Alice Hamilton Visiting Professor, University of California at San Francisco
- 2000-2001 Visiting Professor, Sri Ramachandra Medical College & Research Institute, Chennai, India
- 2004 Visiting Professor, Department of Environmental Medicine, University of Rochester
- 2013 Visiting Professor, Shanghai Key Laboratory, Shanghai Jiao-Tung University

SEMINARS AND EXTRAMURAL INVITED PRESENTATIONS (last 15 years, since 2003; prior presentations upon request)

CV: Howard Hu, M.D., M.P.H., Sc.D.

CV: Howard Hu

24

- 2003 Guest lecturer, "Lead as a trans-generational toxin", Seminar series, Department of OB/GYN, Brigham and Women's Hospital
- 2003 Plenary speaker, "Clinical opportunities in environmental health", Annual Leadership Retreat, National Institute for Environmental Health Sciences, Greensboro, NC.
- 2003 Discussant, "Uncontrolled Hypertension in a Painter", Grand Rounds in Occupational/Environmental Medicine, Harvard School of Public Health
- 2003 Discussant, "A 53-Year Old Teacher with Chemical Sensitivities", Grand Rounds in Occupational/Environmental Medicine, Harvard School of Public Health
- 2003 Lecturer, "Pestilence and Progress: The Future of Public Health through the Lens of Blood", Center for Blood Research Symposium, Museum of Science, Boston, MA.
- 2003 Speaker, "Bones, Genes, Plasma, and Lead: New Frontiers in Understanding the Toxicity of an Old Hazard", Distinguished Lecture Series. National Center for Environmental Health/Agency for Toxic Substances and Disease Registry, Centers for Disease Control and Prevention, Atlanta GA.
- 2003 Plenary speaker, "Biomarkers, Genes, Interactions and Lead: New Insights from Research on an Old Hazard", Superfund Basic Research Program Annual Meeting, Dartmouth University, Hanover, NH.
- 2003 Special Lecturer, "Lead Exposure and Chronic Disease: Recent Research on Susceptible Sub-populations", Florida Agricultural and Mechanical University, Tallahassee, FL.
- 2004 Speaker, "New Frontiers in Understanding the Toxicity of Lead", Department of Environmental Medicine, University of Rochester, Rochester, NY.
- 2004 Presenter, "Lead Exposure During Pregnancy: Mobilization of Maternal Bone Lead Stores and Their Threat to the Fetus", Semi-annual meeting of the Childhood Lead Poisoning Prevention Branch, Centers for Disease Control and Prevention, Baltimore, MD
- 2004 Presenter, "Environmental Medicine", Annual meeting of the Editorial Board, *Environmental Health Perspectives*, Baltimore MD
- 2004 Plenary speaker, "Metals, Genes, and Neurodegeneration: the Approach of the Metals Epidemiology Research Group at the Harvard School of Public Health", National Institute for Environmental Health Sciences Conference on Neurodegeneration.
- 2004 Discussant, "Suspected Lead Toxicity" Grand Rounds in Occupational/Environmental Medicine, Harvard School of Public Health
- 2004 Discussant, "Mercury Exposure in a Metal Worker", Grand Rounds in Occupational/Environmental Medicine, Harvard School of Public Health
- 2004 Presenter, "Effects of Our Environment on Intellect, Behavior, Life and Death," Leadership Council meeting, Harvard School of Public Health
- 2004 Guest Speaker, "Biomarkers, Genes, Interactions and Lead: New Insights from Research on an Old Hazard", Department of Environmental Health, University of Michigan School of Public Health
- 2004 Guest Speaker, "Medicine, Public Health, and the Great American Melting Pot: A Second-Generation Chinese-American Reflects on His Personal Odyssey", Sponsored by the Asian Student Association, Harvard School of Public Health
- 2004 Speaker, "Aging, the Environment and Genetics: Recent Insights from

- Epidemiologic Studies of Environmental Lead Exposure”, Annual Leadership Retreat, National Institute for Environmental Health Sciences, Pinehurst, NC.
- 2004 Plenary Speaker, “Guidelines for the Management of Lead-Exposed Adults: Recommendations by a National Expert Panel Based on Recent Research”, New England College of Occupational and Environmental Medicine Annual Meeting
- 2005 Lecturer, “Biomarkers, Genes, Interactions and Lead: New Insights from Research on an Old Hazard”, Sri Ramachandra Medical College and Research Institute, Chennai, Tamil Nadu, India
- 2005 Lecturer, “Your Child's IQ, Behavior and Neuropathology: Genes or Environment?”, the Harvard Club of Boston, Boston, MA
- 2005 Guest Speaker, “Metals, Neurodevelopment, and Neurodegeneration: The Work of the Metals Epidemiology Research Group at HSPH”, Neurostatistics Working Group, Harvard School of Public Health, Boston, MA.
- 2005 Plenary Speaker, “Aging, the Environment and Genetics: Recent Insights from Epidemiologic Cohort Studies of Environmental Lead Exposure”, NIEHS Symposium on Aging and the Environment, Duke University, Durham, NC.
- 2005 Plenary Speaker, “SPECT Imaging and Chemical Intolerance”, NIEHS/NIAA symposium on “Chemical Intolerance and Addiction: a Shared Etiology?”, Research Triangle Park, NC
- 2005 Workshop Presenter, “Social and Environmental Threats: the Unnecessary Epidemics”, Harvard School of Public Health Leadership Council Annual Conference, Boston, MA
- 2005 Keynote Speaker, “Our Food, Our Water, Our Homes: Toxic Metals”, The Boston Foundation, Boston, MA.
- 2006 Invited Speaker (invited by David Schwartz, NIEHS Director), “Goal IV: Improve and Expand Community-Linked Research”, Roundtable on Environmental Health Sciences, Research, and Medicine; Institute of Medicine, National Academy of Sciences, Wash DC.
- 2006 Speaker, “The Future of Environmental Health Sciences at the University of Michigan”, Dean’s Advisory Board, University of Michigan School of Public Health, Ann Arbor, MI
- 2006 Keynote Speaker and Harriett Hardy Annual Lecturer, “The ‘E’ in Occupational/Environmental Medicine: the Present and the Future”, New England College of Occupational Medicine Annual Meeting, New Bedford, MA
- 2007 Speaker, “The Future of Environmental Health Sciences at the University of Michigan”, Meetings of the UMSPH Alumni Council and the EHS Emeritus Faculty, Ann Arbor, MI
- 2007 Moderator and Speaker, “The Normative Aging Study: Health Effects of Lead”, Symposium on the Health Effects of Lead, 2007 Annual Meeting of the International Society for Environmental Epidemiology, Mexico City, Sept 8, 2007
- 2007 Guest Lecture, “Uncovering the Impact of the Environment on Disease: Big Opportunities for Physician-Scientists”, Medical Scientist Training Program, University of Michigan Medical School
- 2007 Guest Lecture, “Industrialization, Pollution and Public Health in India: Can India Survive Modernization?”, Osher Institute, Ann Arbor, MI
- 2007 Plenary Speaker, “Environmental Equity: Local and Global Challenges and the Balance Between Research and Advocacy”, Michigan’s Premier Public Health Conference,

I, Bruce Lanphear, MD, MPH, declare that:

1. I am a Clinical Investigator at the BC Children's Hospital Research Institute, BC Children's Hospital, and Professor in the Faculty of Health Sciences at Simon Fraser University in Vancouver, British Columbia.

2. I am also the Co-Principal Investigator of an ongoing study to examine the impact of early-life fluoride exposures on intellectual abilities in a cohort of mothers and offspring from Canada known as the MIREC Study. Our study of fluoride and IQ in the MIREC cohort was funded by a grant from the U.S. National Institutes of Health (NIH).

I. SUMMARY OF QUALIFICATIONS

3. A complete summary of my qualifications and publications can be found in my Curriculum Vitae, which has been marked as Plaintiffs' Exhibit 6 and attached herein.

4. I have studied the impact of toxic chemicals, including lead and pesticides, on children's brain development for over 20 years. My research has been almost exclusively funded by federal agencies, including the Environmental Protection Agency (EPA), Centers for Disease Control and Prevention, the Department of Housing and Urban Development, Health Canada, National Institute of Allergy and Infectious Diseases, National Institute for Child Health and Human Development, National Institute of Environmental Health Sciences, National Institute of Neurologic Diseases, and the National Heart, Lung and Blood Institute.

5. My research has been published in leading medical and scientific journals, including *Journal of the American Medical Association*, *New England Journal of Medicine*, and *Pediatrics*, and has been extensively relied upon by environmental and public health agencies, including the EPA. My pooled analysis of blood lead and IQ (Lanphear 2005) was cited by the EPA as the critical study upon which the Agency based the current national air standard for lead.

1 6. I have served on the editorial boards of seven academic journals, including *Public Health*
2 *Reports* (the official journal of the U.S. Surgeon General), *PLoS Medicine* (a peer-reviewed medical
3 journal published by the Public Library of Science), and *Environmental Health Perspectives* (a journal
4 funded by the National Institutes of Environmental Health Sciences).

5 7. I have served on numerous scientific committees on environmental health issues impacting
6 children, including multiple scientific advisory boards for the EPA and the Executive Council on
7 Environmental Health for the American Academy of Pediatrics. My work with the EPA has included
8 invited expert advisory roles on EPA's (i) Science and Research Work Group of the Children's Health
9 Protection Advisory Committee (1998-2001); (ii) Workshop on Assessing Environmental Exposures to
10 Children (2000-2002); (iii) Clean Air Scientific Advisory Committee (2006-2008); (iv) Science Advisory
11 Board for Evaluating Dust Lead Standards (2010-2012); and (v) Science Advisory Board for Evaluating
12 Hazards of Partial Water Line Replacement (2011-2012).

13
14 8. My research has earned various awards and honors, including the Research Integrity Award
15 from the International Society for Environmental Epidemiology in 2012, the Public Policy and Advocacy
16 Award from the Academic Pediatric Association in 2013, and the Research Award from the Academic
17 Pediatric Association in 2015.

18
19 9. I have been involved with the MIREC Study for over 10 years. I was a Co-Principal
20 Investigator for the neurobehavioral assessments conducted when the children were 3 to 4 years old and I
21 oversaw the neurodevelopmental assessments in Vancouver. I have been a coauthor of twelve publications
22 from the MIREC Study, including three publications on fluoride described below.

23
24 10. In light of the consistent association between elevated fluoride and IQ reported in cross-
25 sectional studies (Choi, et al. 2012), we received a grant from the NIH to study the association between
26 prenatal and early-life measures of fluoride and IQ in children in the MIREC cohort. To date, we have
27

1 published three peer-reviewed studies, including the most extensive assessment of fluoride exposure
2 during pregnancy ever conducted and prospective studies on early life fluoride exposure on IQ. These
3 studies have been published in *Environmental Health Perspectives*, *JAMA Pediatrics*, and *Environment*
4 *International* (Till 2018, Green 2019, Till 2020). Our study on prenatal fluoride and IQ was the highest
5 scoring study in *JAMA Pediatrics* in 2019 (Christakis 2020).

6 11. I agreed to participate as a non-retained expert in this case because I believe it is a public
7 duty to present the results of studies that suggest substantial risk to public health. I have asked *not* to be
8 compensated for this work.
9

10 II. SUMMARY OF OPINIONS

11 12. Our study of prenatal fluoride and IQ in the MIREC cohort (Green 2019) further enhances
12 the quality of data related to the neurotoxicity of fluoride. As with the ELEMENT cohort, we employed a
13 prospective cohort design, had extensive control for potential confounders, and had multiple measures of
14 fluoride exposure during pregnancy, including three types of urinary fluoride measurements for each
15 trimester of pregnancy.
16

17 13. The maternal urinary fluoride levels in the MIREC cohort were significantly associated
18 with lower intellectual abilities in 3-4-year-old children. These associations remain large and significant
19 when controlling for relevant covariates.

20 14. Converging results from the MIREC and ELEMENT cohorts indicate that exposure to
21 “optimal” levels of fluoride during fetal development is associated with diminished intelligence in
22 childhood.
23

24 15. In the MIREC cohort, exposure to fluoridated water in infancy, particularly among
25 formula-fed infants, was also associated with diminished intelligence (Till 2020). This association remains
26 significant after controlling for fetal fluoride exposure and other relevant covariates, suggesting that
27

1 susceptibility to fluoride's adverse neurological effects may extend into infancy.

2 **III. BASIS FOR OPINIONS**

3 **A. The Growing Problem with Brain-Based Disorders**

4 16. As I have discussed elsewhere, the causes of death and disability in children have shifted
5 over the past century (Lanphear 2015). Concerted public health efforts to control tuberculosis, cholera,
6 typhoid, and other infectious agents in the early twentieth century led to a dramatic reduction in child
7 mortality, followed by a rise in life expectancy. By the end of the twentieth century, the 'new morbidities
8 of childhood' had emerged: attention deficit hyperactivity disorder (ADHD), autism, asthma, obesity, and
9 preterm birth. Learning disabilities and neurodevelopmental disorders are now two of the most prevalent
10 morbidities in children. About 7.6% of US children are estimated to have a learning disability, and 13%
11 are estimated to have a neurodevelopmental disorder, including anxiety, autism, conduct disorder,
12 depression, or ADHD (Lanphear 2015). These data indicate that we are in the midst of an epidemic of
13 brain-based disorders.
14

15 17. Neurotoxicants can have a lifelong impact on brain function. Children who have higher
16 blood lead concentrations, for example, may never meet the same peak cognitive ability in adulthood as
17 that in less exposed children. At the other end of the age spectrum, cognitive decline is accelerated in
18 adults who have higher bone lead concentrations and some evidence has shown that lead exposure is a
19 risk factor for the development of late-onset Alzheimer's disease. Few birth cohorts have been studied
20 into adulthood; however, it would be surprising if the effects of other neurotoxicants observed in school-
21 aged children do not persist into adulthood (Lanphear 2015). The cumulative impact of exposures to
22 various toxins that only modestly impact intellectual abilities can be substantial (Lanphear 2015).
23

24 18. The high reported prevalence of learning disabilities and neurodevelopmental disorders has
25 fueled research to better understand the role of environmental chemicals, including the use of prospective
26
27

1 cohort studies that collect individualized biomarkers of exposure to environmental toxins. Biologic
2 markers, or biomarkers, of exposure, which can enhance our ability to quantify an individual's internal
3 dose of a contaminant, are revolutionizing the study of environmental toxins in the same way genetic tests
4 are revolutionizing the study of heritability (Lanphear 2015).

5 **B. The MIREC Cohort Is a Comprehensively Characterized Birth Cohort**

6 19. The MIREC¹ cohort in Canada was developed to obtain biomonitoring data for pregnant
7 women and their infants to examine potential adverse health effects of early-life exposure to
8 environmental chemicals.

9 20. The MIREC cohort is a geographically diverse and comprehensively characterized birth
10 cohort. Women were recruited during the first trimester of pregnancy from 10 cities across Canada,
11 including cities that add fluoride to water for caries prevention purposes (e.g., Toronto), and cities that do
12 not (e.g., Vancouver). Women were followed through delivery and their offspring have undergone
13 periodic neurodevelopmental tests, including IQ testing.

14 21. We administered questionnaires during pregnancy and early childhood to collect
15 information on demographics, occupation, lifestyle, medical history, environmental exposures and diet.
16 Dietary questions included whether the mother drank tap water during pregnancy, how many glasses of
17 water and other beverages she consumed, and duration of breastfeeding.

18 22. Information on the pregnancy and the infant was abstracted from medical charts. Maternal
19 urine was collected at multiple points throughout pregnancy, as was blood, urine, hair, breast milk, cord
20 blood and infant meconium. These samples have been archived in a biobank.

21 23. Study staff from each participating study site completed a 3-day training session that was
22

23

25

¹ MIREC stands for Maternal-Infant Research on Environmental Chemicals. It is an
26 interdisciplinary collaboration between Health Canada scientists and clinical and academic researchers,
27 and was funded by Health Canada, the Ontario Ministry of the Environment, and a grant from the
28 Canadian Institutes of Health Research.

led by a PhD-level psychologist and focused on specialized training of the neurodevelopmental tests. The training emphasized the importance of providing an ideal and standardized environment in the home by ensuring that the test area was well-lit, quiet, and free from distractions and interruptions.

C. Urinary Fluoride Study (Till 2018)

24. In 2018, we published the most comprehensive study of urinary fluoride during pregnancy that has ever been conducted (Till 2018). Our study included 1,566 pregnant women from the MIREC cohort who had urine samples for each trimester of pregnancy. It was the first study of its kind in water-fluoridated areas of North America. A similar study has recently been published of a smaller pregnancy cohort in California (Uyghurturk 2020), but our study remains the largest and most thorough.

1. Methodological Strengths

25. Our study of urinary fluoride was conducted in accordance with sound and objective science practices. Important strengths of the study include: (1) a large study size, with over 1,500 women and over 5,000 urine samples; (2) collection of urine samples from each trimester for each mother; (3) empirical data on the actual measured water fluoride levels for each mother's water treatment plant boundary (WTP) during the course of the pregnancy; (4) control for other factors that have potential to influence urinary fluoride excretion, including tea consumption, alcohol use, pre-pregnancy BMI, maternal age, maternal education, annual household income, and race; (5) control for fluctuations that can occur in urine fluoride during the day by adjusting for dilution using two methods (specific gravity and creatinine) and controlling for time of void and time since last void; and (6) measurement of fluoride in urine using the same scientist (Dr. Martinez-Mier), method (microdiffusion), and laboratory (University of Indiana) as the ELEMENT cohort, thereby enhancing the comparability of the data.

26. Dr. Martinez-Mier's lab at the University of Indiana is considered a gold-standard lab for the testing of fluoride in urine and blood. EPA appears to recognize Dr. Martinez-Mier's expertise as she

was approached by EPA to serve as an expert in this case.

2. Fluoridated Water Has a Large and Significant Effect on Urinary Fluoride

27. In our study, fluoride in water had the strongest correlation with urine fluoride of all the factors that we measured, thus confirming that fluoridated water remains a major source of fluoride intake (Till, 2018).

28. The average urinary fluoride level among pregnant women in fluoridated areas is almost two times higher than the average levels in nonfluoridated areas (Till 2018).

29. The average creatinine-adjusted² maternal urinary fluoride level in the fluoridated areas is 0.87 mg/L, versus 0.46 mg/L in the non-fluoridated areas.³

30. Our data suggests that, for every 0.5 mg/L increase in water fluoride level, urinary fluoride levels will increase by 74-82%.

31. Our findings are consistent with prior studies showing that, among adults, fluoride levels in urine are closely correlated with the concentration of fluoride in water.

32. As part of our study, we attached a table showing the full distribution of urinary fluoride levels, including the 75th and 95th percentile exposures for each trimester (Till et al. 2018, Table S4). At the second trimester, 95th percentile values in the fluoridated areas were 2 mg/L (adjusted for creatinine), and 1.63 mg/L (adjusted for specific gravity).

² Creatinine-adjustment of spot urine samples adjusts for dilution and has been found to have good agreement with 24-hour fluoride values (WHO 2014, Zohouri 2006). We used the same method for creatinine adjustment as Bashash (2017). We also adjusted for dilution by correcting for specific gravity. Our adjustments for creatinine and specific gravity produced results that were highly correlated ($r = 0.91$) and interchangeable in our analyses of the factors that increase urinary fluoride.

³ The average specific gravity-adjusted concentration in the fluoridated areas was 0.71 mg/L (SD 0.38 mg/L), with a range of 0.10 to 3.12 mg/L.

3. Pregnant Women in Water-Fluoridated Areas of the MIREC Cohort Have Similar Urinary Fluoride Levels as the ELEMENT Cohort

33. One of the key findings from our 2018 study is that pregnant women who live in water-fluoridated areas of Canada have urinary fluoride levels that are essentially the same as the urinary fluoride levels documented in the ELEMENT cohort.

34. The similarity in maternal urinary fluoride levels between the MIREC and ELEMENT cohorts can be appreciated when comparing the respective mean values (0.87 vs. 0.91 mg/L), standard deviations (0.50 vs. 0.40 mg/L), and ranges (0.14-3.80 vs. 0.02-3.67 mg/L) of the study participants in the water fluoridated areas of the MIREC cohort vs. the ELEMENT cohort.

35. The similarity in maternal urinary fluoride levels between the MIREC and ELEMENT cohorts is of scientific and public health relevance given the findings of Bashash (2017) showing an inverse association between maternal urinary fluoride and offspring IQ.

D. Prenatal Fluoride/IQ Study (Green 2019)

36. In 2019, we published our findings on the relationship between prenatal fluoride exposure and IQ in the MIREC cohort. The study, which was published in *JAMA Pediatrics*, provides reliable and unbiased results and was conducted in accordance with sound and objective science practices.

1. Methodological Strengths

37. ***Prospective Birth Cohort Study Design:*** A key strength with our study is that we used a prospective cohort study design, also known as a longitudinal study. Prospective studies are the best available method for investigating the impact of environmental chemicals and, as noted earlier, have helped to revolutionize our understanding of how chemicals impact childhood health.

38. ***Extensive Control for Potential Confounders:*** The MIREC cohort is one of the most comprehensively characterized birth cohorts, with abundant individualized data on factors that may influence neurodevelopment. We took full advantage of this data. We excluded study participants if there

was a known fetal abnormality, if they had any medical complications (i.e., cancer, renal disease, cardiovascular disease), or if there was known maternal alcohol or drug abuse during pregnancy. For analyses using water fluoride, we excluded women if they did not drink tap water during their pregnancy. For those not excluded, we controlled for the following factors: maternal education; maternal age; quality of the child's home environment (HOME); child sex; mother's race; city of residence; secondhand smoke; maternal blood or urinary concentrations of other neurotoxicants, such as lead, arsenic, mercury, manganese, and PFOA. Additionally, we controlled for the diurnal fluctuations that may occur in urinary fluoride levels by including time of day that the urine sample was collected and time since last void.

39. ***Individualized Measures of Fluoride Exposure:*** Another important strength of our study is that we had multiple individualized measures of prenatal fluoride exposure, including: (1) urinary fluoride samples averaged across each trimester of pregnancy and corrected for urinary dilution; (2) measured water fluoride levels from within each participant's water treatment plant boundary during the course of their pregnancy;⁴ and (3) questionnaire data about how much water each woman drank from tap water and water-based beverages.

40. ***Large, Multi-Center Cohort:*** Our study included 512 mother-offspring pairs which is a robust sample size for statistical analyses. Further, the mother-offspring pairs came from 6 cities across Canada, some of which fluoridate their water (average F = 0.59 mg/L), and some of which do not (average F = 0.13 mg/L).⁵ Our study thus permitted us to examine the impact of fluoride exposures on IQ in communities with water fluoridation, thus addressing what some have perceived to be a limitation of prior

⁴ Water treatment plants measured fluoride levels daily if fluoride was added to municipal drinking water and weekly or monthly if fluoride was not added to water. We matched participants' postal codes with water treatment plant zones, allowing an estimation of water fluoride concentration for each woman by averaging water fluoride concentrations (in milligrams per liter) during the duration of pregnancy.

⁵ Pregnant women in the fluoridated areas tended to have higher incomes and more education, which may help explain the lack of difference in average *unadjusted* IQs between fluoridated and non-fluoridated areas (Green 2019, Table 1).

studies of fluoride neurotoxicity.

41. ***Reliable and Objective IQ Test:*** We assessed children’s intellectual abilities with the Wechsler Preschool and Primary Scale of Intelligence, Third Edition (WPPSI-III). This is a validated IQ test with excellent internal reliability ($r = 0.96$), and good test-retest reliability ($r = 0.86$). We used Full Scale IQ (FSIQ), which is a measure of global intellectual functioning, as the primary outcome. The FSIQ score is comprised of two composite scores: Verbal IQ (VIQ)—representing verbal reasoning and comprehension—and Performance IQ (PIQ)—representing nonverbal reasoning, spatial processing, and visual-motor skills.

42. ***Blinded Assessments:*** As with the ELEMENT cohort, our study was “blinded,” meaning the examiners were not aware of the mother’s fluoride exposure status at the time of the examination. This eliminates the potential for examiner bias.

43. ***Statistical Analyses that Did Not Assume Linearity:*** We conducted sound, objective, and rigorous statistical analyses that: (i) controlled for the impact of the large number of measured covariates; (ii) examined the data for collinearity, outliers, and influential points; and (iii) scrutinized the shape of the relationship between fluoride and IQ. With respect to linearity and possible threshold effects, we conducted sensitivity analyses that used quadratic and natural log effect models as well as ran spline analyses that examined the relationship below 0.5 mg/L, 0.8 mg/L, and 1.0 mg/L in urine (and below 0.4 mg/day and 0.8 mg/day in fluoride intake). We did *not* assume that statistical associations between fluoride and IQ were linear and without threshold.

44. Short of intentionally dosing pregnant mothers with fluoride, we maximized the power of environmental epidemiology to investigate whether prenatal fluoride exposure is associated with neurocognitive deficits in a prospective, observational cohort study.

2. Prenatal Fluoride Exposure Is Associated with Large and Significant Reductions in IQ in the MIREC Cohort

45. All three measures of prenatal fluoride exposure—(i) maternal urinary fluoride, (ii) maternal fluoride intake from beverages, and (iii) water fluoride concentration during pregnancy—were associated with large, statistically significant decreases in IQ among the 3 to 4-year old children in the MIREC cohort.

46. After controlling for covariates, a 1-mg/L increase in maternal urinary fluoride⁶ was associated with a **4.49 lower IQ** score (in boys); a 1-mg higher daily intake of fluoride from beverages was associated with a **3.66 lower IQ** score (in boys and girls); and a 1 mg/L higher water fluoride concentration was associated with a **5.29 lower IQ** score (in boys and girls). These fluoride-associated reductions in IQ that we found showed a linear, dose-response relationship with no apparent indication of a threshold (see figures below).

⁶ We used specific gravity (SG) as the primary adjustment method for this study. The average SG-adjusted concentration among women from the fluoridated areas was 0.69 mg/L (SD = 0.42), which is consistent with the concentration in fluoridated areas from the larger cohort (0.71 mg/L, SD = 0.38) (Till 2018). Sensitivity analyses using the creatinine-adjusted urinary fluoride values did not change the results between fluoride and IQ (Green 2019, eTable 2).

47. The effect sizes that we found are large and rival the impact of a population blood lead concentration of 5 $\mu\text{g}/\text{dL}$.⁷ Fourteen percent of the women had urinary fluoride concentrations exceeding 1.0 mg/L, and thus the impact for some children may exceed the ranges identified above.

48. Although maternal urinary fluoride was associated with significant reduction in full-scale IQ in boys, it was not associated with diminished full-scale IQ in girls. As is often the case, the reason for this discrepancy is not currently known. It is known, however, that boys have a higher prevalence of neurodevelopmental disorders such as ADHD, learning disabilities, and intellectual disabilities than girls. It is also known that boys and girls may respond differently to some neurotoxicants. In our studies of the MIREC cohort, for example, we found that low levels of blood lead correlate with a loss of IQ in boys, but not girls (Desrochers-Couture 2018).

49. The possibility that boys are more sensitive to prenatal fluoride exposure than girls is

⁷ My pooled analysis of blood lead and IQ found that an increase in childhood blood lead from <1 to 10 $\mu\text{g}/\text{dL}$ was associated with a 6.9 IQ point decrement (Lanphear 2015, p. 814). General population exposures to lead today are now on the low-to-mid range of this spectrum, with relatively few children having blood lead levels as high as 10 $\mu\text{g}/\text{dL}$.

supported by at least one animal study, in which males had greater deficits from prenatal exposure and females had greater deficits from postnatal exposure (Mullenix et al 1995). While we did not find sex-specific differences with our other two exposure measures (water F concentration and water F intake), these other measures may better correlate with chronic or postnatal exposure and thereby reflect distinct risks.

3. Convergent Findings of ELEMENT and MIREC Cohorts.

50. The significant associations we observed between prenatal fluoride and IQ in the MIREC cohort are consistent with the findings from the ELEMENT cohort (Bashash, 2017).

51. In the ELEMENT study, an increase of 1 mg/L in creatinine-adjusted maternal urine was associated with a loss of 6.3 IQ points among 4-year olds, as measured by General Cognitive Index (GCI) of the McCarthy Scales of Children's Abilities. In our analysis, an increase of 1 mg/L in creatinine-adjusted maternal urine was associated with a loss of 4.96 IQ points among 3- to 4-year old boys, as measured by the WPPSI-III test (Green 2019, eTable 2). These effect sizes are generally consistent with each other.

52. The consistency of results in both population cohorts adds further confidence that the association is real, particularly when viewed in the context of other studies that have reported inverse associations between fluoride and IQ in many different locations in other countries, as well as general knowledge about the vulnerability of the developing brain.

E. Infant Fluoride/IQ Study (Till 2020)

53. We recently completed and published a study that examined whether fluoride exposures during infancy have an influence on IQ at 3-4 years (Till 2020).

54. Concerns have been raised about the use of fluoridated water in baby formula due to the high intake of water by bodyweight during infancy. These high intakes have been associated with

significant increases in dental fluorosis, including in the permanent teeth.

55. In our study, we obtained information about fluoride intake of infants through questionnaires that the mothers completed when the children were 30 to 48 months of age.⁸ The questionnaire included the question, “How old was your baby when you ceased breastfeeding exclusively?” Women who breastfed exclusively for six months or longer were included in the breastfeeding (BF) group; those who reported introducing formula within the first six months (never breastfed or partial breastfeeding) were included in the formula-feeding (FF) group.

56. As a separate measure of infant fluoride exposure, we estimated fluoride intake by obtaining the measured water fluoride levels within the water treatment plant boundary during infancy. We took the average of these levels, multiplied by the amount of time that the infant was not exclusively breast-fed during the first year,⁹ and divided it by the estimated average water intake among Canadian formula-fed infants (0.8 L). We excluded any mother-offspring pair if the mother reported not drinking tap water.

1. Methodological Strengths

57. Our study of infants shares many of the same methodological strengths as our prenatal study, including: (i) prospective cohort design; (2) extensive control for potential confounders (discussed below); (3) blinded assessment; (4) relatively large cohort (398 mother-offspring pairs) from both fluoridated and non-fluoridated areas; (5) the same validated and standardized IQ test that we used for the prenatal study (i.e., Wechsler Primary and Preschool Scale of Intelligence-III); and (6) rigorous statistical

⁸ The answers to these questions correlated well with the contemporaneous infant feeding practices that were reported among 11% of the cohort. Among women with breastfeeding questionnaire data and infant feeding observation data, the median difference for when breast-feeding ceased was 0 months, with two-thirds being within 1.5 months of each other.

⁹ The mean duration of exclusive breastfeeding was 4.98 months; 13.6% of women reported never breastfeeding, 8% reported discontinuing breastfeeding after the first three months, and 50.2% reported continuing to breastfeed at six months or longer. Average water fluoride concentration did not significantly differ between the BF (mean=0.32 mg/L) and FF groups (mean=0.29 mg/L; p=.18).

analyses that tested for sex-specific effects and scrutinized the impact of outliers and influential points.

58. We adjusted for potential confounding by selecting covariates *a priori* that have been associated with fluoride, breastfeeding, and children's intellectual abilities. Final covariates¹⁰ included child's sex and age at testing, maternal education, maternal race, second-hand smoke in the home, and quality of the child's home environment (measured at time of testing using the Home Observation for Measurement of the Environment (HOME)). We also controlled for fetal fluoride exposure, using the previously measured maternal urinary fluoride concentrations averaged across each trimester of pregnancy.

2. Fluoride Exposure During Infancy Is Associated with Significant Reductions in Non-Verbal IQ in the MIREC Cohort

59. We found that fluoride exposure during infancy is associated with significant reductions in non-verbal IQ in the MIREC cohort.

60. For each 0.5 mg/L increase in water fluoride concentration, we found a decrease of 4.4 Full-Scale IQ (FSIQ) points among preschool children who were formula-fed in the first six months of life; 0.5 mg/L is the approximate difference in mean water fluoride level between fluoridated (0.59 mg/L) and non-fluoridated (0.13 mg/L) regions. In contrast, we did not find a significant association between water fluoride concentration and FSIQ among children who were exclusively breastfed in the first 6 months.

61. The association between water fluoride concentration and FSIQ must be interpreted with caution, however, because the association became nonsignificant when two outliers were removed.

62. We observed an even stronger association between water fluoride and PIQ (non-verbal intelligence). A 0.5 mg/L increase in water fluoride level predicted a decrement in non-verbal IQ in both

¹⁰ For each analysis, a covariate was retained in the final model if its p-value was <0.20 or its inclusion changed the regression coefficient of water fluoride concentration or fluoride intake from formula by more than 10%.

1 the formula-fed (**9.3-points**) and the breastfed groups (**6.2-points**). Adjusting for fetal exposure or
2 removing two extreme scores did not appreciably alter these results.

3 63. We observed converging results using fluoride intake from formula feeding, which is a
4 continuous, time-weighted exposure estimate. For each 0.5 mg/day of fluoride intake, we found an **8.8-**
5 **point** decrement in non-verbal IQ; adjusting for fetal exposure attenuated the association only slightly
6 (**7.6-point** decrement).

7 64. The time-weighted fluoride intake estimate may reflect a more refined measure of exposure
8 in infancy because it captures differences in both water fluoride level and the proportion of time each child
9 was given formula over the first year of life. Yet, our binary classification of whether a child was
10 exclusively breastfed for the first 6 months may distinguish infants who are exposed to higher amounts of
11 fluoride during the early infancy period when the brain undergoes significant development because breast
12 milk contains minutes amounts of fluoride.

13 65. Taken together, these findings suggest that using “optimally” fluoridated water (0.7 mg/L)
14 to reconstitute infant formula may diminish the development of intellectual abilities in young children,
15 particularly non-verbal abilities. The findings also suggest that both prenatal and early childhood fluoride
16 exposure affect the development of non-verbal intelligence to a greater extent than verbal intelligence.
17 Prior studies examining prenatal exposure to fluoride and IQ showed a similar pattern.
18

19
20 **F. The Limitations of Our Studies Do Not Provide a Likely Explanation for the**
21 **Results**

22 66. As with all epidemiological studies, our fluoride studies have limitations. These
23 limitations, however, are unlikely to explain the large and significant associations that we have found
24 between early-life exposures and IQ.

25 67. Most of the limitations in our studies involve fluoride measurement. These limitations
26
27

1 include: (1) use of spot urine samples instead of 24-hour samples;¹¹ (2) lack of water fluoride
2 measurements from the participant's home; (3) reliance on questionnaire data as to water consumption
3 and breast-feeding; (4) lack of information on the fluoride content of the infant formula concentrate and
4 other sources of fluoride exposure; and (5) use of non-validated methods¹² for estimating total beverage-
5 based intake of fluoride by mothers and water fluoride intake by infants.

6 68. The limitations in our exposure estimates are non-differential, meaning they apply equally
7 to study participants with low fluoride exposure and high fluoride exposure. Non-differential errors in
8 exposure measurement will generally bias the results towards the null (i.e., attenuate, rather than inflate,
9 an association between exposure and outcome). Because of this, the limitations in our exposure estimates
10 do not provide a likely explanation for the significant IQ decrements we observed with fluoride exposures.
11 If anything, these limitations likely attenuated the relationship.
12

13 69. Another limitation of our studies is that the MIREC cohort tends to be more affluent, more
14 educated, and less ethnically diverse than the general population. Our results may thus not be
15 representative of how fluoride may affect IQ in more disadvantaged populations. On the other hand,
16 affluent populations tend to have less confounders (e.g., less exposure to other stressors and toxicants that
17 can negatively affect neurodevelopment) (Lanphear 2015). We thus worry less about the role of
18 confounders in the MIREC cohort than we would in other cohorts.
19

20 70. Finally, despite our comprehensive array of covariates included, our studies could not
21 address the possibility of unmeasured residual confounding. This is a limitation in all observational
22

23 ¹¹ A 24-hour sample of urine is considered the optimal dosimeter for measuring chronic fluoride
24 exposure (WHO 2014). While we did not have 24-hour samples available to test, we partially controlled
25 for this by adjusting samples by creatinine. Creatine-adjusted urine fluoride measurements have been
26 found to have a strong correlation with 24-hour samples (Villa 2010; Zohouri 2006).

27 ¹² These methods were not validated in the sense that they have not yet been replicated by other
28 authors in other studies. Our method for assessing fluoride intake from beverages did show internal
validity, however, by predicting maternal urinary fluoride levels. This can be seen in the highly significant
correlations that we found ($p < 0.0001$) between maternal urinary fluoride and number of glasses of water
consumed per day and black tea consumption (see Till 2018).

1 studies, and thus inherent to the field. One of the potential confounders for which we lacked data was
2 maternal IQ. We did, however, control for maternal education which is highly correlated with maternal
3 IQ. Moreover, a greater proportion of women living in fluoridated communities (76%) had a university-
4 level degree compared with women living in nonfluoridated communities (66%), and thus it seems
5 unlikely that controlling for maternal IQ would affect our results, particularly since there is no reason to
6 believe that maternal IQ would be correlated with maternal urinary fluoride.

7
8 71. I understand that the EPA has suggested that the location of our study in Canada somehow
9 reduces the relevance of our findings to populations in the US. I disagree. From a biologic standpoint,
10 there is no credible basis to believe that people in the U.S. will respond differently to fluoride than people
11 in Canada. Nor am I aware of any credible reason to conclude, let alone suspect, that people in water-
12 fluoridated areas of the U.S. are exposed to materially less fluoride than people in water-fluoridated cities
13 of Canada.

14 IV. CONCLUSION

15 72. The collective evidence from prospective cohort studies supports the conclusion that
16 fluoride exposure during early brain development diminishes the intellectual abilities in young children,
17 including at the purportedly “optimal” levels of exposure for caries prevention.
18

19
20 I declare under penalty of perjury, under the laws of the United States, that the foregoing is true
21 and correct to the best of my knowledge and belief.

22 Executed on May 20, 2020, in Vancouver, British Columbia, Canada.

**CURRICULUM VITAE OF
BRUCE LANPHEAR, MD, MPH**

CURRICULUM VITAE

Bruce Perrin Lanphear, MD, MPH

Office Address

Blusson Hall
8888 University Drive
Burnaby, BC V5A 1S6
Canada
e-mail: blanchephear@sfu.ca

Marital status: Married to Nancy Ebbesmeyer Lanphear, M.D., a developmental pediatrician

Citizenship: United States of America and Canada (dual citizenship)

Specialty: Board Certified in General Preventive Medicine & Public Health

Employment

1984-1986	Paramedic, Jackson County Jail, Kansas City, Missouri
1988-1989	Physician, International Travel Clinic, University of Cincinnati, Cincinnati, Ohio
1988-1989	Staff Physician, Sexually Transmitted Disease Clinic, Cincinnati Public Health Department, Cincinnati, Ohio
1989-1992	Assistant Professor of Environmental Health, Associate Director, Medical Center Health Services, University of Cincinnati
1992-1997	Senior Instructor, Departments of Pediatrics and of Community & Preventive Medicine, University of Rochester School of Medicine.
1992-1994	National Research Scholar Award in General Pediatric Research, University of Rochester School of Medicine and Dentistry.
1992-1997	Assistant Professor, Department of Pediatrics and of Community & Preventive Medicine, University of Rochester School of Medicine.
1997-2002	Associate Professor, Department of Pediatrics, Children's Hospital Medical Center and the University of Cincinnati, Cincinnati, Ohio.
1997-2008	Director, General Pediatric Research Fellowship Training Program, Children's Hospital Medical Center and the University of Cincinnati.
1997-2008	Director, Children's Environmental Health Center, Children's Hospital Medical Center and the University of Cincinnati.
1997-2006	Associate Professor (Adjunct), Departments of Pediatrics and of Environmental Medicine, University of Rochester School of Medicine & Dentistry, Rochester, NY.
1998-2003	Associate Director for Research, Division of General & Community Pediatrics, Children's Hospital Medical Center.
2001-2002	Associate Professor (tenured), Department of Pediatrics, University of Cincinnati, Cincinnati, Ohio.
2001-2004	Associate Professor (Adjunct), Department of Environmental Health Sciences, University of Michigan School of Public Health, Ann Arbor, Michigan.
2002-2008	Sloan Professor of Children's Environmental Health, Departments of Pediatrics and Environmental Health, University of Cincinnati, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio.

2008-2012 Adjunct Professor of Pediatrics, Department of Pediatrics, Cincinnati Children's Hospital Medical Center and the University of Cincinnati.
 2008- Professor of Children's Environmental Health, Faculty of Health Sciences, Simon Fraser University
 2008- Clinician Scientist, Child & Family Research Institute, BC Children's Hospital, University of British Columbia

Education

1980-1985 Bachelor of Arts in Biology
 1980-1986 University of Missouri at Kansas City, Medical Degree (1986)
 1986-1987 Internship, University of Arkansas for Medical Sciences, Little Rock, Arkansas
 1987-1988 Tulane School of Public Health & Tropical Medicine
 Masters in Public Health & Tropical Medicine
 1987-1989 General Preventive Medicine and Public Health Residency
 Tulane School of Public Health & Tropical Medicine
 1992-1995 Postdoctoral Fellowship in General Academic Pediatric Research
 University of Rochester School of Medicine, Rochester, NY

Awards and Honors

2011 Sterling Prize in Controversy, Simon Fraser University
 2012 Research Integrity Award, International Society for Environmental Epidemiology
 2013 Public Policy and Advocacy Award, Academic Pediatric Association
 2015 Research Award, Academic Pediatric Association
 2015 Confederation of Union Faculty Associations of British Columbia (CUFA-BC) Academic of the Year Award
 2018 Lumina Award from the Women for Healthy Environmental Health, Pittsburgh, PA

Teaching Experience

1992-1997 Course Instructor, "Public Health & the Environment", Department of Community & Preventive Medicine, The University of Rochester School of Medicine and Dentistry. A required course for MPH students taught annually.
 1997-2008 Founding Director, NIH-funded, General Academic and Community Pediatric Research Fellowship Training Program, Cincinnati Children's Hospital Medical Center. This interdisciplinary, research training program, which included pediatricians, psychologists and epidemiologists, was the first training program in Children's Environmental Health.
 1998-2008 Course Co-Instructor, "Children's Health & the Environment", Department of Environmental Health, The University of Cincinnati School of Medicine. A course taught every other year to MPH, PhD and postdoctoral trainees in medical subspecialties.
 2008- Course Instructor, "Children's Health and the Environment". A 2-week intensive course taught annually to 4th year undergraduate students at Simon Fraser University.
 2011- Course Instructor, "Plagues, Pollutants and Poverty: The Origins and Evolution of Public Health". An undergraduate course at Simon Fraser University.

Committee and Community Involvement

1993-1997	Lead Poisoning Prevention Task Force, Monroe County Health Department.
1994-1997	Investigational Review Board, Rochester General Hospital
1995-	Scientific Consultant, National Center for Healthy Housing, Columbia, Maryland.
1996-1997	Member, New York State Task Force on Environmental Neurotoxins, University of Rochester School of Medicine
1996-2001	Member, National Institute for Environmental Health Sciences Grant Review Committee for Community-Based Interventions (FG)
1996-1998	Chairman, U.S. Department of Housing and Urban Development Committee on Lead-Contaminated House Dust
1998	Member, Review Group for National Research Service Awards, Health Resources and Services Administration
1998-2000	Member, Cincinnati Board of Health, Cincinnati, Ohio.
1998-2001	Member, Science and Research Work Group, Office of Children's Health Protection Advisory Committee, U.S. EPA
1998-2000	Member, Cincinnati Lead Poisoning Prevention Advisory Task Force, Cincinnati, Ohio.
1999	Member, K23 Grant Review Committee, National Institute for Environmental Health Sciences, August 1999
1999	Member, Expert Panel on Soil Pica Behavior, Agency for Toxic Substance Disease Registry, June 7 th -8 th , Atlanta, Georgia
2000	Member, Panel on Health Disparities: Linking Biological and Behavioral Mechanisms with Social and Physical Environments, National Institute for Environmental Health Sciences, July 14-15 th
2000-2002	Member, Workshop on Assessing Environmental Exposures to Children, U.S. Environmental Protection Agency, July 26-27 th
2000-2004	Member, Children's Environmental Health Project, AAP's Child Health Research Center, Rochester, NY.
2001	Senate Testimony, "Ensuring that Children with Dangerous Levels of Lead in their Blood Receive Care as Early as Possible". Subcommittee on Housing and Transportation of the Committee on Banking, Housing and Urban Affairs, 107 th U.S. Congress, November 13 th , 2001.
2001	Reviewer, National Research Council, National Academy of Science Update of the 1999 Arsenic in Drinking Water Report
2001-2003	Member, Expert Panel on Children's Health and the Environment, North American Commission for Environmental Cooperation
2002-	Member, Scientific Advisory Board, Scientist Communication Network.
2003	Member, "Herculaneum Health Study Workshop" Agency for Toxic Substance Diseases Registry, May 22 nd to 23 rd , 2003
2003-2004	Panel Member, "Lead Poisoning in Pregnant Women", Mt. Sinai for Children's Health and the Environment, New York, NY
2003	Member, "Invitational Workshop on a proposed American Family Study" National Human Genome Research Institute, December 1 st to 3 rd , 2003.

2004-2006 Member, Committee on “Ethical Consideration for Research on Housing-Related Health-Hazards involving Children”, National Research Council and the Institute of Medicine, The National Academies

2004 Congressional Testimony, “Tapped Out? Lead in the District of Columbia and the Providing of Safe Drinking Water”, Subcommittee on Environment and Hazardous Materials of the Committee on Energy and Commerce, U.S. House of Representatives, 108th Congress, July 22nd, 2004

2005 Reviewer, “Superfund and Mining Megasites – Lessons from the Couer d’ Alene River Basin”, National Research Council, The National Academies.

2005 Ad Hoc Member, NIEHS Board of Scientific Counselors Review of the Epidemiology Branch, April 3rd to April 5th, 2005

2005 Senate Briefing, “The Connection of Environmental Chemicals and Learning Disabilities”, U.S. Senate, May 10th, 2005

2006 Invited Participant, NIEHS Strategic Planning Forum, National Institute for Environmental Health Sciences, Chapel Hill, North Carolina, October 17-18th, 2006.

2006-2008 Member, U.S. EPA’s Clean Air Scientific Advisory Committee Lead Review Panel.

2006-2008 Member, National Children’s Study Steering Committee, NICHD

2006 Invited Participant, “How Does Housing Affect Health Outcomes of Children?”, MacArthur Foundation, Chicago, Illinois, June 21st-22nd, 2006.

2006- 2010 Member, External Scientific Advisory Committee, Richmond Center for Excellence in Tobacco Research, American Academy of Pediatrics.

2007 Testimony, Vermont State Legislature, “The Lingering Legacy of Lead Toxicity”, Montpelier, Vermont, February 1st, 2007

2007 Testimony, Connecticut State Legislature, “The Legacy of Lead Toxicity”, Hartford, Connecticut, March 14th, 2007. (PG)

2007 Invited Testimony, United States Senate Hearing, “Lead and Children’s Health”. Committee on Environmental and Public Works, October 18th, 2007

2007-2008 Member, Committee on “Committee on Contaminated Drinking Water at Camp Lejeune”, National Research Council, The National Academies.

2008 Member, Expert Panel on Health and the Environment, Statistics Canada, Ottawa,

2008- Member, Alliance for the Global Elimination of Lead Paint, Intergovernmental Forum on Chemical Safety (IFCS), World Health Organization

2008-2009 Reviewer, Toxicological Review and Recommended Toxicological Reference Values for Environmental Lead Exposure in Canada, Health Canada

2009-2013 Scientific Advisor, Canada Lead Study funded by Health Canada (Patrick Levallois, Principal Investigator).

2009-2014 Board Member, Barro Sin Plomo

2009-2010 Member, Health and Environment Experts Advisory Group of the Canadian Longitudinal Study on Aging, Canadian Institutes of Health Research

2010-2012 Member, US Environmental Protection Agency Science Advisory Board for Evaluating Dust Lead Standards

2010-2013 Advisor, Canada Environmental Health Law and Canadian Partnership for Children’s Health and Environment Retrofit Project

2010-2012 Member, Physicians Advisory Panel, Canada Health Measures Survey

2010 Invited Testimony, United States Senate Hearing, “Research on Environmental Health Factors with Autism and Neurodevelopmental Disorders”, August 3rd, 2010

2010 Member, Joint FAO/WHO Expert Panel for Toxicological and Health Review of Bisphenol A

2010-2015 Board Member, Global Community Monitoring, Oakland, California

2010- Chairman, Scientific Advisory Committee for Dartmouth University’s Program in Children’s Health and the Environment

2011-2016	Member, American Academy of Pediatrics Executive Council on Environmental Health
2011-2012	Member, US Environmental Protection Agency Science Advisory Board for Evaluating Hazards of Partial Water Line Replacement
2011	Invited Testimony, Special Committee on Cosmetic Pesticides, Legislative Assembly, Province of British Columbia, October 7 th , 2011
2011-2012	Member, Panel on Health Effects of Low-level Lead, Office of Health Effects, National Toxicology Program of the National Institutes of Environmental Health Sciences,
2012-	Member, Expert Advisory Committee, Canada Health Measures Survey
2012-	Member, Environmental Defence Fund Science Advisory Committee on Toxics
2015	Reviewer, Review of Clinical Guidance for the Care of Health Conditions Identified by the Camp Lejeune Legislation, Institute of Medicine, The National Academies
2016-	Member, The Lancet Commission on Pollution, Health & Development
2016-	Member, Targeting Environmental Neuro-Developmental Risks (TENDR)
2016	Member, Steering Committee, The National Lead Summit, United States
2017	Rockefeller Foundation Academic Writing Retreat, Bellagio, Italy
2017-	Member, Advisory Committee for the Flint (MI) Cohort Study
2017-	Pure Earth Leadership Council
2018-	Member Project TENDR Advisory Board
2018-	Member, Mercury Disability Board Committee, Health Canada

Editorial Boards

2000-2015	Assistant Editor, <i>Environmental Research</i>
2000-2008	Deputy Editor, <i>Public Health Reports</i>
2004	Associate Editor, <i>Pediatrics</i> supplement on Children's Environmental Health
2004-2017	Editorial Board Member, <i>PLoS Medicine</i>
2005-2014	Editorial Board Member, <i>Breastfeeding Medicine</i>
2007-	Editorial Board Member, <i>Environmental Health</i>
2008-2012	Editorial Review Board Member, <i>Environmental Health Perspectives</i>
2012-2015	Associate Editor, <i>Environmental Health Perspectives</i>
2016-	Advisor, <i>Environmental Health Perspectives</i> News Section

Societies and Organizations

1989-2008	American Public Health Association
1996-2015	Academic Pediatric Association
1997-2012	American Association for the Advancement of Science
2000-2008	Society for Pediatric Research
2001-2008	American Pediatric Society
2001-2016	Specialty Fellow, American Academy of Pediatrics
2006-	Fellow, Collegium Ramazzini
2006-	Member, International Society for Environmental Epidemiology
2008-	Founding Member, International Society for Children's Health & the Environment
2011-2017	Secretary and Treasurer, International Society for Children's Health & the Environment
2012-	Member, International Society for Exposure Science
2017-2018	Vice-President, International Society for Children's Health & the Environment
2019-2020	President, International Society for Children's Health & the Environment

88. "The Effects of Low-level Exposure to Environmental Toxins during Fetal Development and Early Childhood", Children's' Hospital of Fudan University, Shanghai International Pediatric Forum, Shanghai, China, June 16th to 18th, 2005.
89. "The Role of Biomarkers in Revealing Genetic and Environmental Influences of Disease and Disability" Psychiatry Grand Rounds, University of Cincinnati, February 8th, 2006.
90. "Trials and Tribulations of Protecting Children from Environmental Hazards: Ethical Issues", Johns Hopkins University of Medicine, March 17th, 2006.
91. "Key Elements of a Primary Prevention Strategy for Lead Poisoning", Albany Law School, Union University, Albany, New York, March 16th, 2006.
92. "Low-Level Lead Toxicity: The Ongoing Search for a Threshold", Case Western Reserve University, City Club of Cleveland, Cleveland, OH March 4th, 2006.
93. Integrating Genetic and Environmental Influences in Pediatric Research" (Moderator and Speaker), Pediatric Academic Societies, San Francisco, CA, April 30th 2006.

94. "Ethical Issues in Housing Health Hazard Research Involving Children" (Topic Symposia) Pediatric Academic Societies, San Francisco, CA, May 2nd 2006.
95. "Low-Level Lead Toxicity: The Ongoing Search for a Threshold", International Workshop on Neurotoxic metals: from Research to Prevention, University of Brescia, Italy, June 17th, 2006.
96. "Efficacy of HEPA-CPZ Air Cleaners on Unscheduled Asthma Visits and Asthma Symptoms", International Society for Environmental Epidemiology, Paris France, September 6th, 2006.
97. "Protecting Children from Environmental Toxins", Region VIII Children's Environmental Health Summit, Vail, Colorado September 20th, 2006.
98. "Integrating Genetic and Environmental Biomarkers in Pediatric Epidemiology", Visiting Professor, Simon Fraser University and University of British Columbia, Vancouver, British Columbia, October 19th-20th, 2006.
99. "The Legacy of Lead", Indiana Lead Conference, Indianapolis, Indiana, October 24, 2006.
100. "Ethical dilemmas in Children's Environmental Health", Seminar Series in Ethics of Toxicology, University of Champagne-Urbana, Champagne, Illinois, November 19th, 2006.
101. "Low-Level Lead Toxicity: Implications for Prevention", WHO Informal Workshop on Lead, University of Munich, Germany, November 30th, 2006.
102. "Low-Level Lead Toxicity: The Ongoing Search for a Threshold", National Environmental Public Health Conference, National Centers for Disease Control, Atlanta, Georgia, December 4th, 2006.
103. "The Epidemiologic Conquest of Childhood Lead Toxicity: A Pyrrhic Victory". NIEHS Workshop on Children's Environmental Health Research: Past, Present and Future. January 22nd, 2007.
104. "Linking Low-level Exposures to Environmental Toxicants with ADHD". Duke Integrated Toxicology and Environmental Health Program Symposium on Developmental Neurobehavioral Disabilities and Toxic Exposures, March 23, 2007, Durham, North Carolina.
105. "Using Biomarkers to Link Environmental Influences with Disease and Disability", The Channing Laboratory, Harvard University, Boston, Massachusetts, April 4th, 2007.
106. "The Lingering Legacy of Lead Toxicity". Grand Rounds, Department of Pediatrics, St. Louis Children's Hospital, St. Louis University, St. Louis, Missouri, April 11th, 2007.
107. "Protecting Children from Environmental Toxicants", United States Council of Catholic Bishops, Washington, D.C., April 30th, 2007.
108. "Efficacy of HEPA-CPZ Air Cleaners on Unscheduled Asthma Visits and Asthma Symptoms", Pediatric Academic Societies, APA Presidential Platform Plenary Session, Toronto, Canada, May 7th, 2007.

109. "The Lingering Legacy of Lead Toxicity" Grand Rounds, Department of Pediatrics, Omaha Children's Hospital, University of Nebraska, Omaha, Nebraska, April 11th, 2007.
110. "Linking Low-level Neurotoxicant Exposures of the Developing Brain to Learning and Behavioral Problems." International Conference on Developmental Programming and Effects of Environmental Toxicants in Human Health and Disease, Faroe Islands, May 20th, 2007.
111. "Protecting Children from Environmental Toxicants: The Neglected Legacy of Rachel Carson", National Policy Consultation Series on Children's Health and Environment, Moncton, New Brunswick, Canada, May 31, 2007.
112. "Low-Level Toxicity of Environmental Toxicants: Much Ado about Nothing?" Occupational and Environmental Health Seminar Series, Health Canada, Ottawa, Canada, June 6th, 2007.
113. "Linking Low-Level Lead Exposure with Child and Adolescent Psychopathology", 13th Annual International Society for Research in Child and Adolescent Psychopathology, London, England, June 19th, 2007.
114. "The Legacy of Lead Toxicity". Pediatric Grand Rounds, New York Presbyterian Hospital-Weill Cornell Medical Center, September 18th, 2007.
115. "Protecting Children from Environmental Toxicants: The Neglected Legacy of Rachel Carson". Pediatric Grand Rounds, Children's Hospital at Dartmouth, Dartmouth Medical School, September 19th, 2007.
116. "The Legacy of Lead Toxicity: Effects of Childhood Lead Exposure in Children, Adolescents and Adults". Mid-America Conference, Philadelphia, Pennsylvania, October 4th, 2007.
117. "Low-Level Toxicity of Environmental Toxicants: Much Ado about Nothing?" International Society for Exposure Analysis (invited plenary session), Raleigh-Durham, North Carolina, October 17th, 2007.
118. The Global Elimination of Lead Toxicity: A Focus on Housing." National Institute of Public Health, Rennes, France, October 22nd, 2007.
119. Linkage of Environmental Lead Exposure with Psychopathology in Children and Adolescents" Ramazzini Collegium, Carpi, Italy, October 25th, 2007.
120. "Linking Exposures to Environmental Toxicants with Child and Adolescent Psychopathology", Symposium on Environmental Toxicity and the Brain, University of Toronto, Toronto, Canada, December 7th, 2007.
121. "Linking Exposures to Environmental Toxicants with Child and Adolescent Psychopathology." Pediatric Grand Rounds, Rochester General Hospital and Strong Memorial Hospital, Rochester, New York, April 1&2, 2008.

122. "Rochester's Role in the Ongoing Elimination of Childhood Lead Toxicity." Beaven Lecture, Rochester Academy of Medicine, Rochester, New York, April 1, 2008.
123. "The Lingering Legacy of Lead Toxicity: Lansing Legacy." Michigan's Conference for Lead Safe & Healthy Homes, East Lansing, MI, April 22, 2008.
124. First Annual Controversies in Pediatric Environmental Health, "Should the Centers for Disease Control Lower the Blood Lead Level of Concern". A debate by Bruce Lanphear and George G. Rhoads (James Sargent, Moderator). Pediatric Academic Societies Meeting, Honolulu, Hawaii, May 2nd, 2008.
125. "Linking Exposure to Environmental Toxicants with Psychopathology in Children and Youth". Visiting Professor, Alberta Child and Youth Network, Calgary Children's Hospital, Calgary, Alberta. May 13th-15th, 2008.
126. "Lead Toxicity and the Teenage Brain", Youth Exploring Science Program, St. Louis Science Center, St. Louis, Missouri, June 30th, 2008.
127. "The Legacy of Childhood Lead Toxicity". Health Canada, Ottawa, Canada, October 6th, 2008.
128. "Protecting Children from Environmental Toxicants: The Neglected Legacy of Rachel Carson". The 2008 Rachel Carson Legacy Conference: Green Chemistry – Solutions for a Healthy Economy, Duquesne University, Pittsburgh, Pennsylvania, September 20th, 2008.
129. "Trials and Tribulations of Protecting Children from Environmental Hazards", Ethics in Toxicology Seminar Series, University of Champagne-Urbana, Champagne, Illinois, September 22nd, 2008.
130. "Industry's Influence on the Prevention of Childhood Lead Poisoning." In: Symposia on Insulating Environmental Health Research from Conflicting Interests. International Society for Environmental Epidemiology Annual Meeting, Pasadena, California, October 14th, 2008.
131. "The Lingering Legacy of Lead Toxicity: Implications for Research and Policy on Other Environmental Toxicants". (Keynote Presentation) BC Environmental and Occupational Health Research Network, Vancouver, BC, November 7th, 2008.
132. "Effects of Environmental Toxicants on Children's Development". DB-PREP Course, American Academy of Pediatrics, Atlanta, Georgia, December 5th, 2008.
133. "Linking Low-level Environmental Toxicants with New Morbidities of Childhood". BC Children's Grand Rounds, British Columbia, Vancouver, February 6th, 2009.
134. "Using Biomarkers to Link Exposures with Disease and Disability in Children". Workshop on Physical and Chemical Exposures in Canadian Cohort Studies, Canadian Institute of Health Research and Health Canada, February 8th-9th, 2009.

135. "How Dangerous Is Lead In Drinking Water?" An interview on "Around The Water Cooler" with Werner Troesken and Bruce Lanphear. February 18th, 2009.
136. "Linking Environmental Toxicants with ADHD in Children" (invited), Learning Disabilities Association Annual Meeting, February 25th, Salt Lake City, Utah.
137. "The Lingering Legacy of Lead Toxicity", Norfolk Children's Hospital, April 30th, 2009, Norfolk Virginia.
138. Second Annual Controversies in Pediatric Environmental Health Debate, "Should Pediatricians Advise Parents to Feed their Children Organic Foods?" A debate by Joel Forman and Janet Silverstein (Bruce Lanphear, Moderator and Organizer). Pediatric Academic Societies Meeting, Baltimore, MD, May 4th, 2009.
139. "A Pattern of Pathology: The Population Impact of Environmental Toxicants on Health". Workshop on Endocrine Disruptors, Endocrine Society, Washington, DC, June 9th, 2009.
140. "The Quandary of Environmental Contaminants in Human Milk", 25th Anniversary of US Surgeon General's Report on Breastfeeding, Washington, DC, June 13th, 2009.
141. "Linking Exposures to Environmental Toxicants with Learning Problems and Psychopathology in Children." Northwest Conference on Children's Health and Environment, Tukwila, Washington, October 1st, 2009.
142. "The Second Coming of the Sanitarians", Pediatric Grand Rounds, University of California at Davis Children's Hospital, Sacramento, California, October 9th, 2009.
143. "The Second Coming of the Sanitarians", National Institute of Public Health, Rennes, France, November 4th, 2009.
144. "Linking Exposure to Environmental Toxicants with ADHD in Children." Symposium on ADHD. Riyadh, Saudi Arabia, November 7th, 2009.
145. "The Interplay of Genetic and Environmental Influences in Common Conditions of Children." Macquarie University, Department of Geology, Sydney, Australia, November 18th, 2009.
146. "The Lingering Legacy of Lead Toxicity: A Call for the Global Elimination of Lead Exposure." Pacific Basin Consortium Symposium on Environment and Health, Perth, Australia, November 13th, 2009.
147. "The Second Coming of the Sanitarians", SFU President's Lecture, Simon Fraser University, Burnaby, BC, March 4th, 2010.
148. Third Annual Controversies in Pediatric Environmental Health Debate, "Should the American Academy of Pediatrics Sponsor a Ratings Board to Provide Evidence-based Ratings for Media?" A debate by James Sargent and Donald Shifrin (Bruce Lanphear, Moderator and Organizer). Pediatric Academic Societies Meeting, Vancouver, BC, May 2nd, 2010.

149. "Efficacy of Reducing Lead Hazards in Housing on Lead-Contaminated House Dust, Blood Lead Concentration and Intellectual Abilities in Children." Pediatric Academic Societies Meeting, Vancouver, BC May 1st, 2010.
150. "Protecting Children from Environmental Toxicants: The Neglected Legacy of Rachel Carson." Pediatric Grand Rounds, Cornell Weill Medical College, New York, New York. May 25th, 2010.
151. "Excavating the Enigmas of Childhood Lead Toxicity", Guest Lecturer, "Introduction to Toxicology, Harvard School of Public Health, Boston, Massachusetts, October 27th, 2010.
152. "The Conquest of Lead Poisoning: A Pyrrhic Victory", Lead Action Collaborative, New England Carpenters Center, Boston, Massachusetts, October 28th, 2010.
153. "Protecting Children from Environmental Toxicants: The Neglected Legacy of Rachel Carson." Academy of Breastfeeding Medicine, San Francisco, California, October 29th, 2010.
154. "Bisphenol A and Behavior Problems in Children". Eastern Perinatal Conference, Kingston, Ontario, November 10th, 2010.
155. "Low-Level Toxicity of Environmental Toxicants: Much Ado about Nothing?" UBC Statistics Department Seminar, November 18th, 2010.
156. "Protecting Children from Environmental Toxicants." Children's Hospital of Quebec, University of Laval, Quebec City, Quebec, December 17th, 2010.
157. "Low-level Toxicity: Implications for Research and Policy", Joint Talks by C. Arden Pope and Bruce Lanphear, SFU, UBC and UW Annual Occupational and Environmental Health Conference, Semiahmoo, WA January 7th, 2011.
158. "Crime of the Century: Lead Toxicity in the 20th Century", Panel Presentation and Discussion, UC Davis, Sacramento, California April 7th, 2011.
159. Fourth Annual Controversies in Pediatric Environmental Health Debate, "Should Parent Slather their Children with Sunscreen?" A debate with Russell Chesney, MD and Sophie Balk, MD, (Bruce Lanphear, Moderator and Organizer). Pediatric Academic Societies Meeting, Denver, Colorado, May 1st, 2011.
160. "The Conquest of Lead Toxicity: A Pyrrhic Victory", Canadian Water Network, Ecole Polytechnique de Montreal, Montreal, Canada, June 9th, 2011.
161. "The Contribution of Environmental Influences on Chronic Disease, Canadian Partnership for Health and Environment, Toronto, Canada, June 16th, 2011.
162. "The Second Coming of the Sanitarians", Environmental and Occupational Health Seminar, University of Washington School of Public Health, Seattle, WA, May 12th, 2011.
163. "Crime of the Century: The Failure to Prevent the Lead Pandemic". Sterling Prize in Controversy, Wosk Centre, Simon Fraser University, Vancouver, BC, October 19th, 2011.

164. "Measuring Exposure: The Benefits and Limits of Biomarkers". Canadian Institute for Human Development, Child and Youth Research, Montreal, Canada, December 6th, 2011.
165. "Rachel Carson: Clarity of Vision". SFU, UBC and UW Annual Occupational and Environmental Health Conference, Semiahmoo, WA, January 6th, 2012.
166. "The Truth About Toxins: What Parents and Health Professionals Should Know". Environmental Influences on Neurodevelopment: Translating the Emerging Science into Public Health Policy". UCLA School of Public Health, Los Angeles, California, January 12th, 2012.
167. "Protecting Children from Environmental Toxicants: The Neglected Legacy of Rachel Carson". Mattel Children's Hospital, Los Angeles, California, January 13th, 2012.
168. "Why Should We Share Data?", Data Sharing Strategies for Environmental Health Workshop, National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina, February 6th and 7th, 2012.
169. "The Science and Prevention of Lead Toxicity" (Keynote Presentation), Forum on Lead Toxicity: A Little is Still Too Much", Macquarie University, Sydney, Australia, June 5th, 2012
170. "Canada Environmental Health Atlas Knowledge Translation Workshop", Canadian Public Health Association, Edmonton, Alberta, June 13th, 2012.
171. "First Annual Controversies in Pediatric Environmental Health Debate: Should organophosphate pesticides be reduced or banned?" A debate with Brenda Eskenazi and Bruce Lanphear (Rob McConnell, Moderator). International Society for Environmental Epidemiology, Columbia, SC, August 28th, 2012.
172. "Supralinear Dose-Response Relationship of Environmental Toxicants: Research and Policy Implications." Moderator and Speaker, with Arden Pope, Roel Vermeulen and Bruce Lanphear. International Society for Environmental Epidemiology, Columbia, SC, August 29th, 2012.
173. Tanya Froehlich and Bruce Lanphear, "ADHD and Environmental Toxicants: Time for Prevention?", Society for Development and Behavioral Pediatrics, Phoenix, AZ, September 9th, 2012.
174. "The Epidemic of Childhood Disabilities: A Failure to Regulate". Workshop on Children's Rights and Corporate Responsibility, Green College, University of British Columbia, Vancouver, BC, October 19th, 2012.
175. "Low-level Toxicity: Much Ado About Nothing?", Department of Preventive Medicine Seminar, University of Southern , California, Los Angeles, California, October 23rd, 2012.
176. "Reflections on Silent Spring". (Invited Keynote). International Society for Exposure Sciences, Seattle, Washington, October 28th, 2012.

177. "Randomized Controlled Trials in Children's Environmental Health: Underutilized or Unethical?" The University of Washington Northwest Pediatric Environmental Health Specialty Unit and Center for Child Environmental Health, Seattle, Washington, February 26th, 2013.
178. "Crime of the Century: Our Failure to Prevent the Lead Pandemic". Dali Lana School of Public Health and of School Environment, University of Toronto, Toronto, Ontario, March 26th, 2013.
179. "The Ongoing Search for a Threshold". International Conference of Toxicology, Seoul, Korea, July 1, 2013.
180. "Blood Lead Concentrations and Cardiovascular Mortality in the United States: The NHANES Mortality Follow-up Cohort Study". International Society for Environmental Epidemiology, Basel, Switzerland, August 2, 2013.
181. "The Conquest of Lead Poisoning: A Pyrrhic Victory". Corporations and Global Health Governance. Simon Fraser University, Burnaby, British Columbia. September 17th, 2013.
182. "Striking at the Root: Changing the Narrative on the Causes of Disease". Corporations and Global Health Governance. Simon Fraser University, Burnaby, British Columbia. September 17th, 2013.
183. "Crime of the Century: The Failure to Prevent the Lead Pandemic". Pacific Basin Consortium, East-West Center, Honolulu, Hawaii. September 26, 2013.
184. "Low-level Toxicity: Policy Implications for the 21st Century". Symposium on Policy Implications of Environmental Exposures in the 21st Century. Pacific Basin Consortium, East-West Center, Honolulu, Hawaii. September 27, 2013.
185. "Excavating the Enigmas of Childhood Lead Toxicity". Network for Soil Contamination Research (INSCR), Delhi University, New Delhi, India. October 22nd, 2013.
186. "The Lingering Legacy of Lead Toxicity: A Call for the Global Elimination of Lead Exposure", World Health Organization, New Delhi, India. October 24th, 2013. "The Environmental Health Atlas: A Portal to Discover the Promises of Environmental Health." National Institute of Environmental Health Sciences, Raleigh-Durham, NC, November 10th, 2013.
187. "Protecting Children from Environmental Toxins". Japan Dioxin and Endocrine Disruptors Preventive Action, Tokyo, Japan, November 24th, 2013.
188. "ADHD: A Preventable Epidemic?" Alberta Children's Hospital, Calgary, Alberta, December 16th, 2013.
189. "Little Things Matter: The Impact of Toxins on the Developing Brain". Early Years Conference, Vancouver, British Columbia, January 30th, 2014.
190. "Little Things Matter: The Impact of Toxins on the Developing Brain". Dalhousie University, Halifax, Nova Scotia, March 6th, 2014.

191. "Low-level Toxicity of Environmental Toxins: Much Ado About Nothing?". Dalhousie University, Halifax, Nova Scotia, March 6th, 2014.
192. "The Canadian Environmental Health Atlas: A Portal to Discover the Promises of Environmental Health." School of Occupational and Environmental Health, University of British Columbia, March 28th, 2014.
193. "Little Things Matter: The Impact of Toxins on the Developing Brain". British Columbia Healthy Child Alliance, Vancouver, British Columbia, April 2nd, 2014.
194. "Sixth Annual Controversies in Pediatric Environmental Health Debate, E-Cigarettes: A weapon in the war against tobacco or a threat to tobacco control. (Moderator). Featuring Greg Connelly and James Sargent. Pediatric Academic Societies, Vancouver, May 4th, 2014.
195. "Striking at the Root Causes of Chronic Disease in Children" (Moderator). James Sargent, Joel Bakan and David Kessler, May 5th, 2014.
196. "Little Things Matter: The Impact of Toxins on the Developing Brain" (Keynote). OHKA Healthy Homes Alliance, Omaha, Nebraska, May 15th, 2014.
197. "Excavating environmental risk factors for autism: Suspects and strategies". A workshop on examining a multi-systems approach to autism and the environment: challenges and opportunities for research". Toronto, Ontario, June 23rd-24th, 2014.
198. "Lead Poisoning: Tackling a Global Problem" (Co-Moderator and Speaker). International Society for Environmental Epidemiology, Seattle, Washington, August 25th, 2014.
199. "Interventions to Reduce Exposures to Environmental Hazards in Pregnant Women and Children", (Moderator and Speaker). International Society for Environmental Epidemiology, Seattle, Washington, August 25th, 2014.
200. 3rd Annual ISCHE-Sponsored Debate: Should there be any restrictions on universities or academicians receiving payment from industry or other sources? (Moderator). International Society for Environmental Epidemiology, Seattle, Washington, August 25th, 2014.
201. "Crime of the Century: Our Failure to Prevent the Lead Pandemic", Tulane University School of Public Health and Tropical Medicine, New Orleans, Louisiana, September 5th, 2014.
202. "Environment Matters", Children's Environmental Health Panel. Society for Environmental Journalists, New Orleans, Louisiana, September 6th, 2014.
203. "Insidious Influence of Industry on Science: How Corporations Undermine Science", 5th Annual C. Everett Koop Distinguished Lecture, "Corporate Threats to Children's Health", with Joel Bakan and James Sargent, Dartmouth University, New Hampshire, October 6th, 2014.
204. "Crime of the Century: Our Failure to Prevent the Lead Pandemic", John Rosen Memorial Lecture, Montefiore Medical Center, New York, New York, October 8th, 2014.

205. "Little Things Matter: The Impact of Toxins on the Developing Brain" (Keynote). Prenatal Environmental Health Education (PEHE) Conference, University of Ottawa. Ottawa, Ontario, November 21st, 2014.
206. "Little Things Matter: The Impact of Toxins on the Developing Brain" (Keynote). ISEE Asian Regional Meeting, Shanghai, China, November 30th, 2014.
207. "Crime of the Century: Our Failure to Prevent the Lead Pandemic", John Rosen Memorial Lecture, ISEE Asian Regional Meeting, Shanghai, China, November 31st, 2014.
208. "Data Visualization", with Joe Braun and Allan Just, Pediatric Environmental Health Scholars Retreat, Reston, VA, December 6th, 2014.
209. "Victories in Public Health: Progress or Adaptation?" SFU, UBC and UW Annual Occupational and Environmental Health Conference, Semiahmoo, WA January 8th, 2015.
210. "Food in the Industrial Era: Is Backward the Way Forward?" Children's Environmental Health Network, Austin, Texas, February 4th, 2015.
211. "Excavating the enigmas of childhood lead toxicity". Broken Hill City Council and Lead Reference Group, Broken Hill, New South Wales, Australia, March 3rd, 2015.
212. "Prevention Paradox: Why a Little Lead is Too Much". Unequal Exposure Symposium, Climate Change Research Center, University of New South Wales, March 5th, 2015, Sydney, Australia.
213. "Crime of the Century: Our Failure to Prevent the Lead Pandemic". 10th Annual Break the Cycle Conference, Emory University, Atlanta, Georgia. April 23rd, 2015.
214. "The Staggering Cost of Lead Toxicity and the Unbelievable Benefit of Preventing It". 10th Annual Break the Cycle Conference, Emory University, Atlanta, Georgia. April 24th, 2015.
215. Seventh Annual Controversies in Pediatric Environmental Health Debate, "GMOs: A Hazard or Harvest of Health?" A debate with Joel Forman, MD and Daniel Goldstein, MD, (Bruce Lanphear, Moderator and Organizer). Pediatric Academic Societies Meeting, San Diego, California, April 27th, 2015.
216. "Impact of Dwellings on Child Health", Canadian Green Building Council Conference, Vancouver Convention Center, Vancouver, BC, April 28. 2015.
217. "Impact of Tobacco on the Developing Brain", Developmental Effects of Nicotine and Implications for Emerging Tobacco Products, Rockville, Maryland, May 5th, 2015.
218. "Impact of Toxins on the Developing Brain" India Tour (Bengaluru, Trivandrum, Kolkata, and Chandigarh) Sponsored by PAN-India, September 4th-11th, 2015.
219. "Impact of Dwellings on Child Health", Green School Summit, Calgary, Alberta, September 25th. 2015.

220. "Prevention Paradox: Why a Little Lead is Too Much", A debate with George Rhoads, Montefiore Medical Center, Tarrytown, October 2nd, 2015.
221. "Crime of the Century: Our Failure to Prevent the Lead Pandemic" (Keynote Presentation), University of Cincinnati Department of Environmental Health 50th Anniversary Gala, Cincinnati, Ohio, October 9th, 2015.
222. "Impact of Toxins on the Developing Brain" (Keynote Presentation) Children's Environmental Health Centers Annual Meeting, Washington, DC, October 31, 2015.
223. "The Impact of Toxins on the Developing Brain: Our Failure to Prevent Brain-based Disorders in Children", National Core for Neuroethics, UBC November 12th, 2015.
224. "Impact of Dwellings on Child Health", Canada Green Building Council, Toronto, ON Green, December 1st, 2015.
225. "The Tortuous Road to Prevention: Are We There Yet", Air Quality and Impacts on Health: Beyond the Heart and the Lungs, The Lung Association of BC, February 28th, 2016.
226. "Lead's Long Shadow: What the Story of Flint, Michigan Means for All of Us", with Bruce Lanphear, Mona Hanna-Attisha and Marc Edwards. Collaborative on Health and the Environment Webinar, March 8th, 2016.
227. "Little Things Matter: The Impact of Toxins on the Developing Brain", Collaborative on Health and Environmental Alaska Working Group Webinar, March 9th, 2016.
228. "Victories in Public Health: Progress or Adaptation?", Symposium Against Indifference, Ashland University, Ashland, Ohio, April 5th, 2016.
229. "Little Things Matter: The Impact of Toxins on the Developing Brain" (Keynote), Children's Environmental Health: New Findings from California Research, Sacramento, California, April 7th, 2016.
230. "Crime of the Century: Our Failure to Prevent the Lead Pandemic", Distinguished Visiting Professor in Health Law, Loyola University, Chicago, Illinois April 21st, 2016.
231. "The Population Impact of Toxins on Intellectual Abilities: Implications for Policy and Prevention", in Symposia on Environmental Toxins and the Brain: Growing Evidence of Risk, Pediatric Academic Societies, Baltimore, MD, May 2nd, 2016.
232. "Data Visualization and Video Production for Public Consumption", in Symposia on Innovative Tools to Enhance Knowledge Translation of Environmental Health: Data Visualization, Videos and Message Mapping, (co-Moderated by Mark Miller and Bruce Lanphear), Pediatric Academic Societies, Baltimore, MD, April 30th, 2016.
233. "Crime of the Century: Our Failure to Prevent the Lead Epidemic", Michigan State University, Flint, MI, May 7th, 2016.

234. "Crime of the Century: Our Failure to Prevent the Lead Epidemic", Johns Hopkins University School of Public Health, Baltimore, MD, May 7th, 2016.
235. "Little Things Matter: The Impact of Toxins on the Developing Brain", Baltimore, MD, International Medical Federation Autism Research (IMFAR), May 8th, 2016.
236. "Public Health Matters: Videos on Toxic Chemicals, Air Pollutants and the Prevention Paradox", Mongolian National University of Medical Sciences, June 23, 2016.
237. "Little Things Matter: The Impact of Toxins on the Developing Brain", USC Annenberg Center for Health Journalism, July 18th, 2016.
238. "Preventing Lead Toxicity", California Environmental Protection Agency, Occupational Environmental Health Hazard Assessment, September 23rd, 2016.
239. "Unleashing the Power of Prevention: Creating Video to Re-Imagine our Approach to Disease," World Issues Forum, Fairhaven College, University of Western Washington, (with Bob Lanphear), November 2, 2016.
240. "Little Things Matter: The Impact of Toxic Chemicals on the Developing Brain", Pediatric Grand Rounds, Maimonides Hospital, November 15th, 2016.
241. "Little Things Matter: The Impact of Toxic Chemicals on the Child Health" (Keynote), Hudson Valley Perinatal Conference, November 16th, 2016.
242. "Little Things Matter: The Impact of Toxins on the Developing Brain", IPEN, San Francisco, CA, November 18th, 2016.
243. "Unleashing the Power of Prevention: Creating Video to Re-Imagine our Approach to Disease", SFU, UBC and UW Annual Occupational and Environmental Health Conference Semiahmoo, WA, January 5th, 2017.
244. "Unleashing the Power of Prevention: Creating Video to Re-Imagine our Approach to Disease", University of New Brunswick, January 25th, 2017.
245. "Little Things Matter: The Impact of Toxic Chemicals on the Developing Brain", New Brunswick Children's Environmental Health Collaborative, January 26th, 2017.
246. "Unleashing the Power of Prevention: Creating Video to Re-Imagine our Approach to Disease", Rockefeller Center, Bellagio, Italy, February 22nd, 2017.
247. "Little Things Matter: The Impact of Toxic Chemicals on the Developing Brain", The Science in Society Speaker Series, Okanagan College, Vernon, BC, April 6th, 2017.
248. "Little Things Matter: The Impact of Toxic Chemicals on the Developing Brain" (invited plenary), Vancouver, British Columbia, Canadian Pediatric Society, June 3rd, 2017.
249. "Unleashing the Power of Prevention: Creating Video to Re-Imagine our Approach to Disease", Macquarie University, Sydney, Australia, September 29th, 2017.

250. "Unleashing the Power of Prevention: Creating Video to Re-Imagine our Approach to Disease", Brown University, Providence, Rhode Island, October 13th, 2017.
251. Cause or Cure: Does the Relentless Pursuit of a Cure Endanger our Health? University of Alaska, Alaska Tribal Health Consortium, Anchorage, Alaska, November 2nd, 2017.
252. "Little Things Matter: The Impact of Toxic Chemicals on the Developing Brain" (Keynote), All Alaska Pediatric Conference, Anchorage, Alaska, November 3rd, 2017.
253. "Little Things Matter: The Impact of Toxic Chemicals on the Developing Brain", CINBIOSE 30th Anniversary, University of Quebec at Montreal, Montreal, November 9th, -10th, 2017.
254. "The Legacy of Lead Poisoning: Moving towards Prevention". East Chicago Community Meeting, Illinois, November 26th, 2017.
255. "Cause or Cure", NIEHS Environmental Health Seminar, University of Southern California, Los Angeles, California, December 1st, 2017.
256. "Little Things Matter: The Impact of Lead on Brain Development" (Keynote Presentation), Workshop on Lead-Free Schools, Pew Trust, Washington, DC, December 6th-7th, 2017.
257. "Low-level Toxicity of Chemicals: No Acceptable Threshold?" Risk Modeling, Mitigation and Modeling in Health Sciences, Centre de Recherches Mathematiques, Montreal, QC, December 11th, 2017.
258. "Little Things Matter: The Impact of Toxic Chemicals on the Developing Brain", Department of Psychology and Neuroscience, York University, Toronto, ON, December 13th, 2017.
259. "The impact of Pollutants on Human Health: No Safe Levels?", Center for Energy and Environmental Contaminants, Macquarie University, Sydney, Australia, February 13th, 2018.
260. "Cause or Cure: Does the Relentless Pursuit of a Cure Endanger our Children's Health?", Department of Pediatrics, University of Wisconsin at Madison School of Medicine, Madison, Wisconsin, March 1st, 2018.
261. "Little Things Matter: The Impact of Toxic Chemicals on the Developing Brain", Wisconsin Environmental Health Network, Madison, Wisconsin, March 2nd, 2018.
262. "Little Things Matter: The Impact of Toxic Chemicals on the Developing Brain", Biennial Atlantic Symposium on Learning Disabilities Association, Fredericton, NB.
263. "Crime of the Century: The Failure to Prevent the Lead Pandemic" (Keynote). 11th UK and Ireland Environmental and Occupational Epidemiology, John Snow Lecture Hall, London School of Hygiene and Tropical Medicine, April 27th, 2018.
264. "The Impact of Pollutants on Human Health: No Safe Levels?" From Toxicology to Planetary Health, London School of Hygiene and Tropical Medicine, April 27th, 2018.

265. Topic Symposium: “Toxic Chemicals and the Rise of Chronic Disease in Childhood: A Preventable Epidemic?” (chair and speaker), Pediatric Academic Societies, May 7th, 2018.
266. “Prevention Paradox; Why a Little Lead is Too Much”, Ontario Water Advisory, Toronto, CA, May 7th, 2018.
267. “How the Secrets of Body Care and Cleaning Products Impact your Health”, Panel with Bruce Lanphear, Muhannad Malas and Janie McConnell, Centre for Free Expression, Ryerson University, Toronto, ON, May 7th, 2018.
268. “Prevention Paradox; Why a Little Lead is Too Much” (Keynote), Pittsburgh, PA, Get the Lead Out Conference, May 9th, 2018.
269. “Low-level Lead Exposure and Mortality”, Global Health Forum, Miami, FL, May 23rd, 2018.
270. “Unleashing the Power of Prevention: Targeting Toxic Chemicals and Pollutants”, Canadian Public Health Association, Montreal, QC, May 28th, 2018.
271. “The Impact of Pollutants on Human Health: No Safe Levels?” Chemicals Management Plan Stakeholder Advisory Council, Health Canada, May 30th, 2018.
272. “Little Things Matter: The Impact of Toxic Chemicals on the Developing Brain”, Pediatric Grand Rounds, University of California – Davis, Sacramento, CA, June 8th, 2018.
273. “Why a Little Lead is Too Much”, Health Canada, Ottawa, ON, August 29th, 2018.
274. “Unleashing the Power of Prevention: Mobilizing Science to Prevent Disease”, ISEE-ISES Workshop, Ottawa, ON, August 30th, 2018.
275. “The Lingering Legacy of Lead: Why a Little Lead is Too Much”, LA Lead Summit: A Strategy for Prevention, University of Southern California, September 14th, Los Angeles, CA.
276. “Little Things Matter: The Impact of Toxic Chemicals on the Developing Brain”, Children’s Hospital of Orange County, Orange County, CA, September 19th, 2018.
277. “The Lingering Legacy of Lead: Why a Little Lead is Too Much”, Hurley Medical Center, Flint, Michigan, October 3rd, 2018.
278. “Lead and The Mysterious Decline in Coronary Heart Disease”, National Institute of Occupational Safety and Health, Cincinnati, OH, October 11, 2018.
279. “Little Things Matter: The Impact of Toxic Chemicals on the Developing Brain”, Grand Rounds, Oregon State Health University, Portland, OR, October 23, 2018.
280. “The Impact of Pollutants on Human Health: No Safe Levels?” Oregon Environmental Council, Portland, OR, October 23, 2018.
281. “Little Things Matter: The Impact of Toxic Chemicals and Organic Food on Children’s Health”, HIPP Scientific Symposium on Organic Food, Kranzberg, Germany, October 30, 2018.

282. “The Mysterious Decline in Coronary Heart Disease”, Harvard University Lead Summit, Cambridge, MA, November 15th, 2018.
283. “The Impact of Pollutants on Human Health: No Safe Levels?” Department of Epidemiology, UMass, Amherst, MA, November 16th, 2018.
284. “Little Things Matter: The Impact of Toxic Chemicals on Human Health”, School of Public Health, Oregon State University, Corvallis, Oregon, April 12th, 2019.
285. Why A Little Lead is Too Much: An Intimate History”, “The Impact of Pollutants on Human Health: No Safe Levels?”, Graduate Course in Environmental Health, School of Public Health, University of California, Berkeley, April 17th, 2019.
286. “The Impact of Pollutants on Human Health: No Safe Levels?”, Department of Environmental Health, School of Public Health, University of California, Berkeley, April 17th, 2019.

Grants

Active Grant Awards

1. Consultant (Joseph Braun, PI). Early Life Perfluoroalkyl Substance Exposure and Obesity: Mechanisms and Phenotyping. 02/01/2016-01/31/2021. National Institutes of Health, \$523,725 (5% effort). The purpose of this award is to study the impact of exposure to perfluoroalkyl chemicals on the development of child obesity, adverse cardiometabolic markers and gene regulation. (2.5% effort)
2. Co-Applicant (Linda Booij, Maryse Bouchard PI). In utero exposure to Bisphenol-A and the developing brain in humans: A longitudinal study of epigenetic mechanisms. 03/01-2016 – 03/31/2019. Canadian Institutes of Health Research (CIHR), \$344,025. (2.5% effort).
3. Principal Investigator (Multiple PI Award with Christine Till). “Impact of early life fluoride exposure on cognitive and behavioural outcomes in children”. NIEHS, 09/30/16 – 05/01/19, \$296,683 (10% effort).
4. Consultant (Aimin Chen, Principal Investigator). Developmental neurotoxicity of organophosphate and novel brominated flame retardants in children. National Institute for Environmental Health Sciences. 1RO1ES028277. 09/30/2017-06/30/22 (10% effort).
5. Mentor (Cynthia Curl, Principal Investigator). Measurement of Agricultural and Dietary Glyphosate Exposure among Pregnant Women. National Institutes of Environmental Health Sciences. 1KO1ES028745-01A1. 09/01/2018-08/31/2022 (5% effort).

Past Grant Awards

1. Principal Investigator, "Dust-Lead and Blood Lead Levels among Urban Children". The National Center for Lead-Safe Housing, \$561,619, 06/15/93 to 08/31/94. Department of Housing and Urban Development Contract MDLPT0001-93. (25% effort).
2. Principal Investigator, "Determinants of Lead Exposure among Children in Monroe County, NY", NIEHS Pilot Grant, University of Rochester School of Medicine and Dentistry, Department of Environmental Medicine. \$7,600, 06/15/93 to 12/31/95. (0% effort)
3. Principal Investigator, "The Effectiveness of Dust Control in Reducing Children's Blood Lead Levels" U.S. Department of Housing and Urban Development, \$128,394, 04/01/94 to 05/30/95. (25% effort).
4. Principal Investigator, "Primary Prevention of Exposure to Lead". Centers for Disease Control and Prevention, \$832,228, 09/30/94 to 10/01/98. (25% effort)
5. Principal Investigator, "Lead-Contaminated House Dust and Children's Blood Lead Levels". National Center for Lead-Safe Housing, \$43,260, 10/01/96 to 03/30/96. (25% effort).
6. Co-investigator (Christy, PI), "Tuberculosis Screening in Children". New York Department of Health, \$15,000, 01/01/95 to 12/31/96. (0% effort)
7. Co-investigator (Weitzman, PI), "Fellowship Training in General Pediatrics" (Grant # D28PE50008). Bureau of Health Professions, HRSA, U.S. Public Health Service, \$1,752,816, 06/01/96 to 05/30/97. (10% effort).
8. Principal Investigator, "Neurobehavioral Effects of Low-Level Childhood Lead Exposure". University of Rochester School of Medicine & Dentistry, \$8,560, 06/01/96 to 05/30/97. (0% effort)
9. Principal Investigator, "Neurobehavioral Effects of low-level Lead Exposure in Children". NIEHS Pilot Grant, University of Rochester Department of Environmental Medicine, \$20,035, 09/01/97 to 08/30/97. (0% effort).
10. Co-investigator (Howard, PI), "Effect on Breastfeeding of Pacifiers and Bottle Feeding". Bureau of Maternal and Child Health, \$420,333, 10/01/96 to 09/30/00. (2.5% effort)
11. Co-investigator (Canfield, PI) "Lead and Children's Cognitive Functioning", Research Grants Program, Cornell University. \$17,000, 10/01/96 to 09/31/97 (0% effort).

12. Principal Investigator, "Neurobehavioral Effects of Low-Level Lead Exposure in Children" (RO1-ES 08338). National Institute of Environmental Health Sciences, 12/01/96 to 11/31/01, \$1,946,848. (25% effort).
13. Co-investigator, (Aligne, PI). "Reduction in Passive Smoking among Children with Asthma: A Randomized Trial of HEPA Air Filtration." 10/01/96 to 09/31/97, \$6,000. KIDD Grant, Rochester General Hospital (0% effort).
14. Co-investigator, (DeWitt, PI). "Faculty Development in General Pediatrics". Bureau of Health Professions, Health, Department of Health and Human Services 07/01/97 to 06/30/00, \$338,000. (15% effort).
15. Principal Investigator, "A Side-by-Side Comparison of Allergen Sampling Methods", U.S. Department of Housing and Urban Development, 01/02/98 to 12/31/98, \$163,065. (15% effort).
16. Principal Investigator, "National Research Service Award - Fellowship Training in General Pediatrics and Adolescent Medicine" (1T32PE10027), Health Resources and Services Administration, DHHS. 07/01/98 to 06/30/03. \$634,408. (0% effort).
17. Co-investigator, (Steiner, PI) "Survey of Directors and Graduates of NRSA Fellowship Training Programs", Health Resources and Services Administration, Department of Health and Human Services. 06/01/98 to 06/30/99.
18. Principal Investigator, "Effect of Soil Remediation on Children's Blood Lead Levels in Midvale, Utah". U.S. Environmental Protection Agency, 08/01/98 to 07/30/99. \$62,550. (15% effort).
19. Co-investigator, (Phelan, PI) Trends and Patterns in Playground Injuries among U.S. Children." Ambulatory Pediatric Association, 05/05/99 to 05/04/00. \$9,000 (0% effort).
20. Principal Investigator, "Risk Assessment for Residential Lead Hazards". U.S. Department of Housing and Urban Development, 09/01/99 to 08/30/00. \$102,435. (25% effort).
21. Principal Investigator, "Residential Exposures associated with Asthma in U.S. Children and Adolescents" U.S. Department of Housing and Urban Development, 07/16/99 to 03/15/00. \$30,400. (20% effort).
22. Principal Investigator, "Effectiveness of Lead Hazard Control Interventions – A Systematic Review" National Center for Lead-Safe Housing, 10/01/99 to 06/01/00. \$22,500 (10% effort).
23. Principal Investigator, "Racial Disparity in Blood Lead Levels due to Genetic Variation in Calcium Absorption". NIEHS Pilot Grant, Center for Environmental Genetics, University of Cincinnati, 04/01/00 to 03/31/01. \$28,130 (0% effort).
24. Principal Investigator, "International Pooled Analysis of Prospective, Lead-Exposed Cohorts". National Institute of Environmental Health Sciences, National Institutes of Health, 08/15/00 to 09/14/01, \$16,000. (2.5% effort).

25. Principal Investigator, "A Randomized Trial to Reduce ETS in Children with Asthma" (RO1-HL/ES65731). National Heart, Lung and Blood Institute, National Institutes of Health, 09/29/00 to 09/28/04, \$1,546,848. (25% effort).
26. Co-investigator, (Geraghty, PI) "Breastfeeding Practices of Mothers of Multiples". Ambulatory Pediatric Association, 05/01/01 to 04/30/02. \$5,000 (0% effort).
27. Principal Investigator (Subcontract), "A Longitudinal Study of Lead Exposure and Dental Caries". National Institute of Dental and Craniofacial Research, National Institutes of Health, 08/01/01 to 07/30/04. \$300,000 (10% effort).
28. Co-investigator (Phelan, PI), "Fatal and Non-Fatal Residential Injuries in U.S. Children and Adolescents" U.S. Department of Housing and Urban Development, 03/01/01 to 11/31/01. \$40,700. (5% effort).
29. Principal Investigator, "Prevalent Neurotoxicants in Children" (PO1-ES11261). National Institute for Environmental Health Sciences and U.S. Environmental Protection Agency, 09/01/01 to 09/31/06, \$5,000,000. (30% effort).
30. Principal Investigator, "International Pooled Analysis of Lead-Exposed Cohorts". Centers for Disease Control (RO1/CCR 521049). Centers for Disease Control, 09/15/01 to 09/14/02, \$28,473. (3% effort).
31. Principal Investigator, supplement to "Prevalent Neurotoxicants in Children" (PO1-ES11261). NIEHS, 09/01/02 to 09/31/07, \$1,800,000. (10% effort).
32. Co-Investigator, "ADHD Phenotype Network: Animal Model to Clinical Trial". National Institute of Neurologic Diseases, 09/15/02 to 06/30/05 (15% effort).
33. Principal Investigator, "Linkage of ADHD and Lead Exposure", Springfield, Ohio Department of Health, 02/01/03 to 06/01/04, \$25,000. (0% effort).
34. Co-investigator (Yolton, PI) "Explorations of ETS Exposure on Child Behavior and Sleep" NIEHS, 04/01/04 to 03/30/06, \$300,000. (5% effort).
35. Co-investigator (Haynes, PI) "MRI as a Biomarker of Manganese Exposure". NIEHS, 09/01/04 to 08/30/06, \$300,000. (5% effort).
36. Co-investigator (National Center for Healthy Housing, PI) "Development of a Standardized Housing Assessment for Asthma", U.S. Department of Housing and Urban Development, 11/01/05 to 10/31/07, \$50,000. (5% effort).
37. Co-Investigator (Hershey, PI) "Epithelial Genes in Allergic Inflammation" National Institutes of Allergy and Infectious Diseases", 07/01/06 to 06/30/07, \$4,787,541. (3% effort).

38. Co-Investigator and Mentor (Wilson, PI), "Racial Difference in DNA Adducts in Tobacco-Exposed Children". Dean's Scholar Award, University of Cincinnati, 02/22/06 to 01/21/09, \$150,000 (5% effort).
39. Principal Investigator, "National Research Service Award - Fellowship Training in Primary Care Research," (1T32PE10027), Health Resources and Services Administration, DHHS. 07/01/98 to 06/30/08. \$1,600,000. (0% effort).
40. Co-Investigator and Mentor (Kahn, PI). "Childhood Asthma in an Era of Genomics: Will the Generalist's Role be Recast?" Robert Wood Johnson Generalist Physician Faculty Scholars Program" 06/01/04 to 05/30/08, \$300,000.
41. Co-Investigator and Mentor (Spanier, PI), "Exhaled Nitric Oxide to Manage Childhood Asthma". National Heart, Lung and Blood Institute, 07/01/06 to 06/31/08, \$200,000 (10% effort).
42. Co-investigator (Sub-Contract PI), BYPL Vanguard Center (Specker, Principal Investigator), "National Children's Study", National Institute for Child Health and Development, 11/01/05 to 10/31/10, \$500,000. (20% effort). [Relinquished with relocation to SFU].
43. Associate Director and Co-Investigator, (Ho, PI). "Center for Environmental Genetics," NIEHS, 04/01/08 to 3/31/13, \$1,000,000 (10% effort). [Relinquished with relocation to SFU.]
44. Co-Investigator (Yolton, PI). "Tobacco Smoke and Early Human Behavior". Clinical Innovator Award, Flight Attendant Medical Research Institute", 07/01/07 to 06/30/10, \$300,000. (3% effort).
45. Co-Investigator (Spanier, PI). "Low Level Prenatal Tobacco Exposure and Infant Wheeze." Young Clinical Scientist Award, Flight Attendant Medical Research Institute, 07/01/07 to 06/30/12, \$300,000. (5% effort).
46. Co-Investigator and Mentor (Spanier, PI). K23, "Prenatal Low Level Tobacco & Phthalate Exposure and Childhood Respiratory Health". National Institute for Environmental Health Sciences, 12/1/07 to 11/30/12, \$623,679 (0% funded effort).
47. Co-investigator (Yolton, PI). "Neurobehavioral effects of insecticide exposure in pregnancy and early childhood." NIEHS, 09/01/09 to 08/31/12.
48. Principal Investigator (Bruce Lanphear, PI), "A Community-Based Trial to Prevent Lead Poisoning and Injuries," National Institute for Environmental Health Sciences, 04/01/07 to 03/30/13, \$2,000,000. (25% effort).
49. Co-Investigator (Kim N. Dietrich, PI). "Early Lead Exposure, ADHD & Persistent Criminality: Role of Genes & Environment," National Institute for Environmental Health Sciences, 04/01/07 to 3/31/2013, \$1,250,000. (2.5% funded effort).

50. Co-Investigator and Sub-Contract PI (Brenda Eskenazi, PI). This supplemental award was to conduct a pooled analysis of prenatal organophosphate pesticide exposures with birth outcomes and neurodevelopment in children using 4 US birth cohorts. NIEHS, 09/01/2009 to 08/31/2013, \$96,000 (0% effort).
51. Mentor and Supervisor (Glenys Webster, PI). Michael Smith Foundation for Health Research Postdoctoral Training Award, 03/01/12 to 02/28/15, \$134,500 (5% effort).
52. Co-Principal Investigator (Tye Arbuckle, PI). Maternal-Infant Research on Environmental Chemicals: Effects on Child Development (MIREC-CD). 06/26/11 to /5/25/14, Health Canada Chemical Management Program, \$283,000 (10% effort).
53. Co-Investigator (Patti Dods and Amanda Wheeler, co-PIs). Phthalate Exposure and the development of asthma in the CHILD Study. 06/01/11 to 05/30/14, Health Canada Chemical Management Program, \$204,000 (5% effort). Consultant (Stephanie Engel, PI). A pooled investigation of prenatal phthalate exposure and childhood obesity. 11/01/2012 – 10/31/15, NIEHS. \$275,000. (5% effort).
54. Co-Investigator (Ryan Allen, PI). A randomized air filter intervention study of air pollution and fetal growth in a highly polluted community. 06/08/2012 – 05/30/15, CIHR \$348,000 (10% effort).
55. Co-Investigator (William Fraser and Tye Arbuckle, co-PIs). MIREC-CD Biomonitoring Study in Vancouver. 09/01/2013 – 08/30/2014. Health Canada, \$120,138 (10% effort).
56. Principal Investigator. Knowledge translation tools for capacity building for an online Canadian Environmental Health Atlas. 03/01/12 – 02/28/13, Canadian Institutes of Health Research, \$98,974 (10% effort).
57. Principal Investigator (with Lawrence McCandless). Prenatal exposure to environmental contaminants and fetal growth: How to account for multiplicity when testing multiple statistical hypotheses?. 07/01/2015-06/30/2016. Canadian Institutes of Health Research (CIHR), \$12,000 (5% effort).
58. Principal Investigator, Canadian Environmental Health Atlas Knowledge Translation to produce videos and interactive tools. 06/01/2015-07/30/2016. Canadian Internet Registration Authority, \$50,000 (10% effort).
59. Co-Investigator (Kieran Phelan, PI). “Injury Prevention in a Home Visitation Population”. NICHD, 09/28/10 to 07/31/16, \$2,000,000 (total direct costs over 5 years) (10% effort).
60. Co-applicant (Timothy F. Oberlander, PI). Developmental origins of autism: A population level linked data study of prenatal antidepressant medication exposure. 09/01/2013 – 09/31/2016, Canadian Institutes of Health Research (CIHR), \$285,768.

61. Principal Investigator (Multiple PI Award with Aimin Chen and Kimberly Yoltan).
“Longitudinal study of exposures to PBDEs and PFCs and child behavior”. NIEHS,
04/30/11 – 05/01/17, \$2,150,000 (total direct costs over 5 years) (20% effort).
62. Principal Applicants (McCandless and Lanphear). Biostatistical methods for estimating the
cumulative impact of environmental contaminant exposures on preterm birth. Canadian
Institute for Human Development, Child and Youth Health. 12/06/16-12/05/18, \$200,000
(10% effort).
63. Co-investigator (Ryan Allen, PI). Randomized Interventions to Evaluate the Effects of Air
Pollution Exposure on Children's Health and Development. 03/01/2015 – 03/31/2019,
Canadian Institutes of Health Research (CIHR), \$720,535. (10% effort)
64. Co-investigator (Joseph Braun, PI). Endocrine Disrupting Chemicals, Thyroid Hormones
and Child Neurobehavior. 06/01/2015-03/31/2019. National Institutes of Health, \$471,241
(5% effort). The purpose of this study is test if and when early life exposures to phthalates,
triclosan, or bisphenol A adversely impacts children’s cognition and behavior.
- 65.

Ethics Training for Research

CITI (Collaborative Institutional Training Initiative) (Reference# 7159023). Academic and Regional
Health Centers Curriculum Course, completed on December 16th, 2011.

CITI (Collaborative Institutional Training Initiative) (Reference# 7160515), Canada GCP Curriculum
Course, completed on December 16th, 2011.

CITI (Collaborative Institutional Training Initiative) (Reference# 8316270), Human Subjects Core
Curriculum, completed on August 17th, 2012.

CITI (Collaborative Institutional Training Initiative) (Reference# 13561457), Academic and Regional
Health Centers Core Curriculum, completed on September 1st, 2014.

CITI (Collaborative Institutional Training Initiative) (Reference# 16954900), Human Subjects Research
Core Curriculum, completed on October 31st, 2015.

	APPENDIX B. Resume of Kathleen M. Thiessen, Ph.D.	125

I, Kathleen Thiessen Ph.D., declare that:

1. I am a risk assessment scientist at Oak Ridge Center for Risk Analysis in Oak Ridge, Tennessee. For more than 30 years, I have been involved in the evaluation of exposures, doses, and risks to human health from trace levels of contaminants in the environment, including fluoride, and in the use of uncertainty analysis for environmental and health risk assessment.

2. I was asked to apply risk assessment frameworks used by the Environmental Protection Agency (EPA) to the current scientific literature on fluoride neurotoxicity to determine whether neurotoxicity is a hazard of fluoride exposure, and whether this hazard is a risk at the levels of fluoride added to drinking water for fluoridation (0.7 mg/L).

I. SUMMARY OF QUALIFICATIONS

3. A complete summary of my qualifications and publications can be found in my Curriculum Vitae, which has been marked as Plaintiffs' Exhibit 7 and attached herein.

4. In the course of my work as a risk assessment scientist, I have done work for the U.S. Environmental Protection Agency (EPA), the U.S. Department of Energy, the Centers for Disease Control and Prevention, the U.S. Nuclear Regulatory Commission, the National Cancer Institute, and the National Institute for Occupational Safety and Health, as well as a number of other government and private clients.

5. I have authored several reports for the EPA on the health effects of specific environmental contaminants, including Health Issue Assessments of fluorides (hydrogen fluoride and related compounds) and mercuric chloride.

6. More recently, I served on two subcommittees of the National Research Council, one which was asked by EPA to review the toxicologic literature on fluoride (which resulted in the 2006 publication *Fluoride in Drinking Water: A Scientific Review of EPA's Standards*), and one

dealing with guidance levels for air contaminants in submarines. For the latter review, published in 2009, the NRC asked me to write much of the chapter on hydrogen fluoride.

7. Recently, I led the Working Group on Assessment of Exposures and Countermeasures in Urban Environments for the International Atomic Energy Agency's (IAEA) program on Development, Testing and Harmonization of Models and Data for Radiological Impact Assessment. I was also involved in the preparation of an IAEA guidance document on implementation of remediation strategies following accidental releases of radioactivity.

8. Throughout my career, I have authored or contributed to a number of open literature publications in peer-reviewed journals such as *Environmental Science and Technology*, *Environmental Pollution*, *Atmospheric Environment*, *Journal of Environmental Radioactivity*, and the *International Journal of Occupational and Environmental Health*. I have also served as a peer reviewer for journals such as *American Journal of Preventive Medicine*, *Environment International*, *Environmental Pollution*, *Risk Analysis*, *Science of the Total Environment*, *Environmental Health Perspectives*, and *Journal of Environmental Radioactivity*, among others.

II. SUMMARY OF OPINIONS

9. Under EPA's *Guidelines for Neurotoxicity Risk Assessment*, there is sufficient evidence to conclude that neurotoxicity is a hazard of fluoride exposure.

10. The animal data on fluoride neurotoxicity are consistent with the epidemiological data in showing a risk of cognitive deficits at doses of fluoride ingested from fluoridated water.

11. Fluoridation chemicals present an "unreasonable risk" of neurotoxic effects, including IQ loss, if assessed under the same risk characterization and risk determination framework that EPA uses in its evaluations of other chemicals under TSCA.

III. SUMMARY OF METHODOLOGY

A. Risk Assessment

12. EPA has stated it “will follow” its *Guidelines on Neurotoxicity Risk Assessment* (hereafter, *Guidelines*) when “evaluating data on potential neurotoxicity associated with exposure to environmental toxicants.”¹ I conducted a risk assessment in accordance with these *Guidelines*, including a Hazard Characterization, Quantitative Dose Response Analysis, Exposure Assessment, and Risk Characterization.

13. Hazard Characterization: Pursuant to the *Guidelines*, I conducted a Hazard Characterization, in which I considered: (1) the animal studies on neuroanatomical, neurochemical, and behavioral effects, including effects on learning and memory; (2) human case reports, including clinician observations of occupationally exposed workers; (3) human epidemiology studies of fluoride and cognitive deficits, including all prospective cohort studies; (4) the literature on fluoride’s neuroendocrine effects; (5) animal and human research on possible modes of action (direct and indirect) by which fluoride affects the brain; (6) dose-response data on fluoride and neurotoxic outcomes in animal and epidemiological studies; (7) the toxicokinetics of fluoride, including data on placental transfer and uptake into the brain; and (8) *in vitro* studies investigating fluoride’s effects on brain cells, including several that used low concentrations.

14. Quantitative Dose Response Analysis: Since the literature demonstrates with high confidence that neurotoxicity is a hazard of fluoride exposure, I turned to the second step of an EPA neurotoxicity risk assessment: Quantitative Dose Response. In a quantitative dose-response analysis, a “Point of Departure” (POD) is identified from the available animal and human data in order to derive a dose that will be without appreciable risk (i.e., a Reference Dose, or RfD). For

¹ EPA (1998a), p. 1.

my analysis, I focused on the animal data, as I understood that Dr. Grandjean had already calculated a POD (i.e., BMDL) from the human birth cohort data.

15. To increase confidence in the risk characterization (a later step in the analysis, discussed below), I did not identify just one POD from the animal data. Instead, I identified the full range of PODs that can be justified, including the *least protective*. After converting these PODs into Human Equivalent Doses (HED), I applied different combinations of uncertainty factors (from non-conservative to conservative) to derive the *full range of reference doses that can be justified from the animal literature*.

16. Exposure Assessment: Consistent with the *Guidelines*, I conducted an Exposure Assessment that focused solely on the condition of use at issue in this case: fluoridation of drinking water. For my initial assessment, I relied primarily, but not solely, on the National Research Council's estimates of fluoride intake from water from the 2006 report. In response to criticisms that NRC's data may no longer be representative of contemporary exposures, I considered EPA's 2019 assessment of water intake data, in which the Agency identified the most scientifically sound and up-to-date data to use for risk assessment. I compared these updated values from EPA with the values I initially used to see if they have any material effect on my risk estimates (they did not).

17. Risk Characterization: Consistent with the *Guidelines*, I integrated the information on hazards and exposures in a risk characterization by, among other things, conducting a "Margin of Exposure" analysis for each of the PODs identified through the Quantitative Dose Response analysis.

18. Risk Determination: For the risk determination, I considered the risk-related factors that EPA has identified as relevant for risk determinations under TSCA. At the time of my initial report, EPA had not yet issued any draft risk evaluations under Section 6 of TSCA, so I relied for

guidance on risk evaluations that EPA had completed under Section 5. In response to criticism on this point, I reviewed the draft risk evaluations that EPA has subsequently issued under Section 6 to assess whether the factors EPA considers under Section 6 affect my initial determination (they do not).

B. Materials Relied Upon

19. For my risk assessment, I have relied upon my background, training and expertise in risk assessment, as well as my existing familiarity with the scientific literature on fluoride, which I first developed through extensive literature reviews for both the EPA and NRC. I also considered the following materials:

20. EPA documents, including (i) the *Guidelines* and other guidance documents that EPA has issued on risk assessment; (ii) risk assessments that EPA has conducted pursuant to the *Guidelines*;² (iii) risk evaluations that EPA has conducted under TSCA; and (iv) EPA's water intake data.

21. The NRC's review of the toxicologic literature on fluoride (NRC 2006), which I co-authored.

22. Animal studies on fluoride neurotoxicity that have been published since the NRC's 2006 review, which I obtained through a search of the National Library of Medicine's online database PubMed, as described further below.

23. The NTP's systematic review of studies addressing fluoride's impact on learning and memory in animals (NTP 2015, NTP 2016).

24. All prospective cohort studies on fluoride and neurodevelopment in humans

²I obtained the complete list of risk assessments that EPA has conducted pursuant to the *Guidelines* via an interrogatory response produced by EPA, which was provided to me by counsel.

(Bashash et al. 2017; Bashash 2018; Broadbent et al. 2015; Green et al. 2019; Shannon et al. 1986; Till et al. 2020; and Valdez-Jiminez et al. 2017).

25. Meta-analyses of the cross-sectional studies on fluoride and IQ (Choi 2012, Duan 2018).

26. The deposition of Dr. Kristina Thayer, the Director of EPA's Integrated Risk Information System (IRIS) and principal author of the NTP's 2015 and 2016 systematic reviews.

27. The deposition of Casey Hannan, the Acting Director of the Oral Health Division of the Centers for Disease Control and Prevention.

28. The deposition of Dr. Tala Henry, the Deputy Director of EPA's Office of Pollution Prevention and Toxics.

29. Studies provided by counsel—much of which I was already familiar with—which I understand were also provided to EPA's experts as well, including Dr. Tsuji.

C. Literature Search for Animal Neurotoxicity Data

30. For the animal literature, I conducted a search of the National Library of Medicine's online database PubMed to identify studies published since the NRC's 2006 review. The search terms used were: "fluoride and brain," "fluoride and learning," and "fluoride and memory."

31. The titles of all studies published since 2006 were reviewed to identify potentially relevant primary studies, and, among potentially relevant studies, abstracts were reviewed to verify relevance. Reviews, studies in Chinese for which translations were not available, and *in vitro* studies were excluded. Full-text copies of all relevant studies were obtained. In total, the search identified 110 papers. Papers that appeared to be reporting effects from the same underlying rodent experiment were treated as one study, leaving 105 distinct studies.

32. The 105 studies I identified are not an exhaustive list of the studies published since

2006, as they do not include studies that were not indexed in PubMed (e.g., studies published in the journal *Fluoride* or in certain Chinese-language journals such as the *Chinese Journal of Endemiology*). In addition, the search terms probably did not identify all relevant studies available on PubMed.

Nevertheless, the studies obtained through this pre-defined search protocol should be a reasonably representative sample of the recent literature.

D. Systematic Review

33. I did not conduct a formal systematic review, but a risk assessment under the *Guidelines* has been considered the effective equivalent of a systematic review.

IV. HISTORIC CONTEXT: 1930s to 2006

34. The early epidemiological studies in the U.S. that claimed to establish the safety of waterborne fluoride (fluoride concentrations ranging from 1 to 8 mg/L in drinking water) did not address the potential for fluoride to cause neurological effects, including IQ loss.³ The primary focus of these early studies was, instead, on skeletal health.

35. Although largely overlooked, some of the early studies of occupationally exposed workers,⁴ as well as some of the early studies of fluoride-exposed animals,⁵ reported central nervous system effects from fluoride exposure. In a 1953 study of monkeys, Wadhwani and Ramasway reported that monkeys with chronic fluorosis “did not conduct themselves with intelligence and agility of mind normally associated with them. There was a significant lack of co-ordination in their behaviour.”⁶ These early observations, some of which remained unpublished,

⁴ Roholm (1937); Popov et al. (1974); Duan et al. (1995); Guo et al. (2001); Yazdi et al. (2011).

⁵ Wadhwani and Ramasway (1953); Lu et al. (1961); Rice and Lu (1963); Sadilova et al. (1968).

⁶ Wadhwani and Ramasway (1953).

were largely ignored at the time.

36. The first known study of fluoride and intelligence in humans was published in 1989 by Ren and colleagues in China.⁷ A flurry of similar studies were published in China in the 1990s.⁸ Most of these studies were published in Chinese, and they remained largely unknown outside of China until English translations started to become available after the NRC's report in 2006.

37. In 2006, the NRC concluded that "fluorides have the ability to interfere with the functions of the brain and the body by direct and indirect means."⁹ The NRC reached this conclusion based on the histological, biochemical, and molecular findings from animal studies published in the 1990s and early 2000s.¹⁰ The NRC also reviewed two studies that examined the impact of fluoride on learning and memory in animals, but the data were not yet sufficient to draw conclusions on cognitive effects.¹¹

38. As part of its report, the NRC also reviewed the 4 studies on fluoride and intelligence that were then available in English.¹² Various methodological limitations were identified with these studies, but the NRC concluded that the consistency of the results (i.e., reduced intelligence among children exposed to elevated fluoride) warranted further epidemiological research into the potential of fluoride to lower IQ.

39. The NRC also reviewed the toxicologic literature on fluoride's effects on the endocrine system, including the thyroid gland. The NRC concluded that fluoride is an endocrine-disrupting chemical which can alter thyroid function at estimated average intakes as low as 0.01 to

⁷ Ren et al. (1989).

0.03 mg/kg/day in individuals with iodine deficiency.¹³ The NRC recognized the potential relevance of fluoride's endocrine effects to neurotoxicity, noting that depressed thyroid function during pregnancy can lower the IQ of the offspring.¹⁴

40. The NRC's findings on the neurotoxic potential of fluoride have been accepted as an accurate summary of the hazard by the EPA and other federal agencies, including the CDC.

41. My risk assessment builds upon NRC's hazard determinations by considering the large volume of additional research that has been published since the NRC findings were released.

V. HAZARD CHARACTERIZATION

A. The "Sufficient Evidence" Standard

42. The focus of the Hazard Characterization is whether, at some level of exposure, the chemical has a credible potential to cause neurotoxic effects (i.e., whether neurotoxicity is a *hazard* of the chemical). The question of whether this hazard is a *risk* at environmentally relevant exposures is a separate question that is addressed in the Risk Characterization phase (as discussed below).

43. Under the *Guidelines*, hazard assessment is a qualitative determination in which the risk assessor must determine whether "sufficient evidence" of a neurotoxicity hazard exists.¹⁵ A "sufficient evidence" finding "can be based on either human or animal data."¹⁶ EPA has a preference for using human data if suitable data exist;¹⁷ in practice, however, animal data are almost always used.¹⁸

¹³ NRC (2006), pp. 262-263, 266.

¹⁴ NRC (2006), p. 263.

¹⁵ EPA (1998a), pp. 11, 53, 55-56.

¹⁶ EPA (1998a), p. 11.

¹⁷ EPA (2018a), p. 2-1.

¹⁸ EPA (1998a), p. 20.

1. Sufficient Evidence from Human Data

44. For human data, “sufficient evidence” of a neurotoxic hazard exists if epidemiologic studies show that “some neurotoxic effect is *associated* with exposure.”¹⁹ EPA contrasted this requirement of an “association” with what the Agency recognized to be the “more stringent requirement” of “causality.”²⁰ Under the *Guidelines*, there is no requirement to prove causality; evidence of an association is enough.

45. In assessing whether epidemiological studies demonstrate an association with neurotoxicity, EPA has stated that prospective cohort studies “should weigh heavily” in the assessment.²¹ The *Guidelines* recognize that prospective studies are “invaluable for determining the time course for development of dysfunction” and permit “direct estimate of risks attributed to a particular exposure.”²² The only drawback of prospective studies that the *Guidelines* identify are that they “can be very time-consuming and costly.”²³

2. Sufficient Evidence from Animal Data

46. For animal data, “sufficient evidence” of a neurotoxic hazard exists if experimental studies demonstrate a potential neurotoxic hazard in humans.²⁴ The “minimum evidence” necessary to demonstrate a potential hazard is “a single appropriate, well-executed study in a single experimental animal species.” If no individual study is sufficient to establish a hazard, “the total

²⁴ EPA (1998a), p. 53.

available data may support such a conclusion” including data on toxicokinetics²⁵ and mechanisms of action.²⁶

47. Neurotoxic endpoints in animal studies fall into several categories, including neuroanatomical, neurochemical, and behavioral.²⁷

48. Neuroanatomical endpoints include changes to the brain, including damage to brain cells, that are detectable under a microscope (i.e., “histological”).²⁸ The *Guidelines* consider neuroanatomical changes to be “of concern,” and EPA has established reference doses for chemicals based on neuroanatomical effects.

49. Neurochemical effects include biochemical changes, such as alterations in neurotransmitter function and effects on enzymes. The *Guidelines* state that neurochemical changes “may be regarded as adverse because of their known or presumed relation to neurophysiological and/or neurobehavioral consequences.”²⁹

50. Behavioral changes include alterations to motor activity, changes in sensory abilities or motor coordination, and impairments in learning, memory, and attention.³⁰ EPA has repeatedly based reference doses on behavioral alterations documented in animals, including learning and memory impairments.

51. In considering the relevance of the animal data to humans, the *Guidelines* provide four default assumptions. First, EPA assumes that “an agent that produces detectable adverse

²⁵ The *Guidelines* use the term pharmacokinetics. Both pharmacokinetics and toxicokinetics refer to the uptake, distribution, and retention of chemicals, with the former term being more frequently used in the context of pharmaceuticals, and the latter term more frequently used in the context of toxicants.

³⁰ EPA (1998a), p. 21.

neurotoxic effects in experimental animal studies will pose a potential hazard to humans.”³¹ Second, EPA assumes that neuroanatomical, neurochemical, and behavioral changes “are of concern.”³² Third, EPA assumes that “the neurotoxic effects seen in animal studies may not always be the same as those produced in humans” due to “species-specific differences in maturation of the nervous system, differences in timing of exposure, metabolism, or mechanisms of action.”³³ Fourth, EPA assumes that “humans are as sensitive as the most sensitive animal species tested.”³⁴ These four assumptions are “plausibly conservative,” meaning that “they are protective of public health and are also well founded in scientific knowledge about the effects of concern.”³⁵

3. Data that EPA Has Found Sufficient for Hazard Determination

52. EPA has conducted 10 risk assessments pursuant to the *Guidelines*. In 9 of these risk assessments, EPA found sufficient evidence to make a hazard determination and established Reference Doses (RfDs) or Reference Concentrations (RfCs)³⁶ to protect against the hazard.³⁷ In each of these 9 assessments, EPA based its hazard determination on animal data. For 6 of these 9 assessments, the chemicals had *no* human data on neurotoxicity (Table 1). For the 3 chemicals with some human data, no prospective cohort studies were available.

53. The principal studies³⁸ which EPA has used to establish RfDs have not been

³¹ EPA (1998a), p. 6.

³² EPA (1998a), p. 6.

³³ EPA (1998a), p. 7.

³⁴ EPA (1998a), p. 7.

³⁵ EPA (1998a), p. 7.

³⁶ Reference Doses refer to oral exposures, while Reference Concentrations refer to inhalational exposure. Eight of the 9 neurotoxicity risk assessments established RfDs, while 1 set an RfC. For purposes of simplicity, I will refer to Reference Doses for the remainder of this declaration when discussing these assessments.

³⁷ These 9 risk assessments were performed for BDE-47 (EPA 2008a), BDE-99 (EPA 2008b), BDE-153 (EPA 2008c), BDE-209 (EPA 2008d), Chlorine Dioxide and Chlorite (EPA 2000b), 2-Hexanone (EPA 2009b), Methanol (EPA 2013a), RDX (EPA 2018a), and Trimethylbenzenes (EPA 2016).

³⁸ A principal study is the study that contributes most significantly to the assessment of risk and is generally the basis for the Point of Departure from which a reference value is derived.

“perfect” studies. In fact, in most of the neurotoxicity risk assessments, EPA has identified a number of methodological limitations with the studies. Some of the principal studies did not conform to EPA’s testing guidelines for animal studies; some used relatively small numbers of animals (e.g., 10 per group); and the principal studies that investigated effects from prenatal exposures did not always control for “litter effects,” a methodological deficiency that can skew the effect size in developmental studies. In light of these limitations, EPA had “low confidence” for the studies it relied upon for several of its risk assessments (see Table 1). This did not stop EPA from establishing RfDs for these chemicals.

54. In several of EPA’s neurotoxicity risk assessments, EPA established an RfD despite a relatively small number of animal studies. In the RDX risk assessment, for example, EPA identified 16 animal studies, only two of which had been published. EPA characterized these studies as showing “consistent evidence” of neurotoxicity because 11 of the 16 studies reported neurological effects³⁹ and the effects were generally dose-related (although inconsistencies existed across the studies in terms of the doses that produced effects).⁴⁰ EPA has thus recognized that “consistency” of the evidence is not synonymous with unanimity.

³⁹ EPA (2018a), p. 1-23.

⁴⁰ EPA (2018a), pp. 1-12, 1-18.

Table 1. Chemicals with oral RfDs based on neurological endpoints, assessed according to EPA's Guidelines for Neurotoxicity Risk Assessment.^a

Name of Chemical	Human Neurotoxicity Data? ^b	Principal Study	Confidence in Principal Study	Known Mode of Action?	Effect	Reference
BDE-47	No	Animal	Not given ^c	Inadequate data	Changes in spontaneous motor activity and habituation	EPA (2008a)
BDE-99	No	Animal	Not given ^d	Inadequate data	Neurobehavioral developmental effects; changes in motor activity	EPA (2008b)
BDE-153	No	Animal	Not given ^e	Inadequate data	Spontaneous behavior, learning and memory	EPA (2008c)
BDE-209	No	Animal	Low	Inadequate data	Changes in spontaneous behavior and habituation	EPA (2008d)
Chlorine Dioxide and Chlorite	No	Animal	Medium	No	Neurodevelopmental delay; lowered auditory startle amplitude	EPA (2000b)
2-Hexanone	No	Animal	Medium	Yes	Axonal swelling in peripheral nerves	EPA (2009b)
RDX	One cross-sectional study, 16 case reports	Animal	High	Yes	Convulsions	EPA (2018a)
Trimethylbenzenes	Occupational studies of solvent mixtures, controlled experiments with healthy adults	Animal	Low to Medium	Tentative, based on structurally similar compounds	Decreased pain sensitivity	EPA (2016)

^a EPA (1998a); Federal Register (1998). In addition, an inhalation RfC was derived for methanol based on animal data (EPA 2013a); the confidence in the RfC was considered medium to high.

^b Human studies of neurotoxicity endpoints.

^c Confidence in the principal study was not stated, but the "overall confidence in the RfD assessment of BDE-47 is low" (EPA 2008a, p. 48).

^d Confidence in the principal study was not stated, but the "overall confidence in the RfD [for BDE-99] is low" (EPA 2008b, p. 67).

^e Confidence in the principal study was not stated, but the "overall confidence in the RfD assessment for BDE-153 is low" (EPA 2008c, p. 37).

55. EPA has taken a similar approach to animal data in some of its draft risk evaluations under Section 6 of TSCA. In its NMP risk evaluation, for example, EPA based its risk calculations for chronic exposures in humans on animal data linking NMP to reduced fertility, despite the fact that there were only six animal studies available, three of which found no effect.⁴¹ These contradictory findings were considered a source of uncertainty, but did not stop EPA from using these animal data to assess risk in humans. In fact, EPA made findings of unreasonable risk in humans exposed to lower doses of NMP based on this small body of contradictory data.

B. Human Studies on the Neurotoxicity of Fluoride

56. As noted earlier, the *Guidelines* state that prospective cohort studies “should weigh heavily in the risk assessment process.”⁴² The *Guidelines* also identify other types of human studies that can inform the assessment, including case reports and cross-sectional studies.⁴³

57. In contrast to 9 chemicals for which EPA has established reference doses under the *Guidelines*, there are abundant human data on fluoride neurotoxicity, including 4 high-quality prospective cohort studies with individualized measurements of exposure during the prenatal period.⁴⁴

58. I understand that Dr. Hu and Dr. Lanphear will be addressing the ELEMENT and MIREC birth cohort studies, and I understand that Dr. Philippe Grandjean will be addressing the other epidemiological studies, so I will forego repeating the details here.

⁴¹ EPA (2019d), pp. 173-174.

⁴² EPA (1998a), p. 17.

⁴³ EPA (1998a), pp. 15-16.

⁴⁴ Bashash et al. (2017; 2018); Green et al. (2019); Valdez-Jiménez et al. (2017).

59. As I described in my expert report, the human data on fluoride *strongly* support a hazard determination. Most importantly, each of the 4 prospective studies with measurements of *prenatal* exposure has found large and significant adverse associations with neurodevelopment, including IQ loss and inattention. An additional prospective study has found an association between IQ deficits and fluoride exposure during *infancy*.⁴⁵ These studies—which have consistently detected a significant association between early-life fluoride exposure and cognitive deficits using the most reliable study design identified by the *Guidelines*—are by themselves enough to constitute “sufficient evidence” of a hazard.

60. The consistency of the inverse association between fluoride and IQ in cross-sectional studies also adds important weight to the hazard assessment. Although cross-sectional studies are limited in their capacity to establish causal relationships, this limitation is lessened where the study examines stable populations and stable water fluoride levels.⁴⁶ In any event, the focus of the *Guidelines* is on assessing whether there is a reliable *association* with neurotoxicity, not on definitively proving causality.⁴⁷ As several meta-analyses have demonstrated, the cross-sectional studies show large and significant inverse *associations* between fluoride and IQ, with an average loss of about 7 IQ points.⁴⁸

61. Finally, the case reports of neurological symptoms following fluoride exposure (e.g., general malaise, fatigue, headaches, and difficulties with concentration and memory) add

⁴⁵ Till et al. (2020).

⁴⁶ Under these conditions, measurement of current water fluoride levels may be a reasonable, albeit imperfect, proxy for exposure from the prenatal period onward, and thus the temporality requirement for a causal inference is partially met. A number of the cross-sectional studies on fluoride and IQ have, in fact, expressly limited the study population to children who lived in the same area since birth, which increases the basis for inferring causation. Chen et al. (1991); Choi et al. (2015); Ding et al. (2011), Karimzade et al. (2014a; 2014b); Khan et al. (2015); Lu et al. (2000); Nagarajappa et al. (2013); Rocha Amador et al. (2007); Seraj et al. (2012); Sudhir et al. (2009); Wang et al. (2007); Yao et al. (1996; 1997); Zhang et al. (2015b).

⁴⁷ EPA (1998a), p. 53.

⁴⁸ Choi et al. 2012; Duan et al. 2018.

additional support to the hazard determination. While case reports are generally not sufficient, by themselves, to establish a hazard, the *Guidelines* consider them “useful when corroborating epidemiological data are available.”⁴⁹ Further, as the NRC noted, several of the case reports on fluoride can be characterized as “experimental studies,” since they involved “individuals who underwent withdrawal from their source of fluoride exposure and subsequent re-exposures under ‘blind’ conditions. In most cases, the symptoms disappeared with the elimination of exposure to fluoride and returned when exposure was reinstated.”⁵⁰ There is credible evidence, therefore, that for some sensitive individuals, fluoride exposure may cause overt neurological symptoms, although the NRC called for more research to better understand the issue.

C. Animal Studies on Fluoride Neurotoxicity

62. The animal research on fluoride neurotoxicity was sufficient to permit the NRC to conclude, in 2006, that fluoride interferes with the functions of the brain.⁵¹ The NRC based this finding on the neuroanatomical and neurochemical changes produced by fluoride in laboratory animals. These changes include: reduced protein and phospholipid content; inhibition of acetylcholinesterase; interference with neurotransmitters; increased production of free radicals in the brain (i.e., oxidative stress); neuronal deformations; increased uptake of aluminum; and enhancement of reactive microglia.⁵²

63. Many animal studies have been published since the NRC review which add further support to the hazard determination, as I will now discuss.

1. Studies Indexed by the National Library of Medicine (PubMed)

64. In my search of PubMed, I identified 105 studies that have been published since

⁴⁹ EPA (1998a), p. 15.

⁵⁰ NRC (2006), pp. 208-209.

⁵¹ NRC (2006), p. 222.

⁵² NRC (2006), pp. 221-222.

2006. Of these studies, all but 4 reported associations between fluoride exposure and neurotoxic outcomes.⁵³

65. Table A-1 in Appendix A to this declaration provides data from the 88 animal studies which investigated neuroanatomical and neurochemical endpoints (i.e., “structural” effects), while Table A-2 provides data from the 36 animal studies which investigated learning and memory endpoints (i.e., “functional” effects).⁵⁴ Twenty-nine studies investigated both types of effects and are in both lists.⁵⁵

66. As can be seen in Table A-1, rodent studies published since the NRC review have continued to document structural (e.g., neuroanatomical and neurochemical) changes in the brains of fluoride-treated rodents. These changes include oxidative stress, neuronal degeneration, mitochondrial disturbances, reductions in nicotinic receptors, impaired synaptic plasticity, and neuroinflammation.

67. Among the studies that have investigated both structural and functional effects of fluoride, the former have sometimes (but not always) occurred at lower exposures, suggesting that fluoride can cause cellular and biochemical changes in the brain prior to the manifestation of outwardly demonstrable deficits.⁵⁶ Put another way, deficits in learning and memory likely represent a relatively advanced stage of fluoride neurotoxicity. Nevertheless, both structural and

⁵³ Negative results were reported by Whitford et al. (2009), Pulangan et al. (2018), McPherson et al. (2018), and Jia et al. (2019, which I discuss later.

⁵⁴ For purposes of simplicity, I have used the term “structural” to refer to both neuroanatomical and neurochemical effects. While neurochemical effects are technically “functional” in nature, I use the word “functional” to refer solely to outward manifestations of neurotoxicity (i.e., learning/memory deficits). In this declaration, therefore, “structural” changes refer to all changes observed *in the brain*, while functional effects refer to all changes in *outward behavior* (e.g., learning and memory test performance, etc).

⁵⁵ To facilitate comparisons across these studies, Tables A-1 and A-2 exclude 2 studies of non-rodents as well as four studies in which the fluoride exposure was part of a mixture involving other potentially neurotoxic chemicals, one study involving exposure by a route other than ordinary ingestion, and two behavioral studies with endpoints that did not specifically involve learning and memory.

⁵⁶ See, for example, Agustina et al. (2018); Ma et al. (2015); Niu et al. (2018a); Sun et al. (2018); Wang et al. (2018a); Zhang et al. (2019); Zhao et al. (2019).

functional harms have repeatedly been observed in rodents at water fluoride concentrations between 5 mg/L and 23 mg/L.⁵⁷ As with the RDX literature,⁵⁸ there are some inconsistencies across the studies in the reported doses that can cause certain types of harm; these differences likely result, at least in part, from differences in study design, including differences in timing of exposure, duration of exposure, and strain and sex of animal.

68. Most of the animal studies to date have used subchronic exposure scenarios, which would tend to understate the effect from lifetime exposure. EPA's testing guidelines define a chronic exposure study in rodents as one that lasts at least 12 months.⁵⁹ None of the recent learning studies has lasted 12 months, and only 1 of the recent structural studies has lasted 12 months or more.⁶⁰ Among the studies that have tested animals at multiple points in time, the effects have tended to worsen with time, with some effects not appearing at all until 3 to 6 months of chronic exposure.⁶¹ Since most of the studies on fluoride neurotoxicity have lasted no longer than 3 months, the studies are likely not detecting the full spectrum of fluoride's effects.

69. I understand that EPA is asserting that systemic toxicity, as reflected by reduced body weight, may explain fluoride's observed effect on learning/memory in animals. The *Guidelines* provide that, "If several neurological signs are affected, but only at the high dose and in conjunction with other overt signs of toxicity, including systemic toxicity, *large decreases in body weight*, decreases in body temperature, or debilitation, there is less persuasive evidence of a direct neurotoxic effect."⁶² The *Guidelines* further provide that "At doses causing moderate

⁵⁷ These concentrations of fluoride *ion* correspond to a concentration of approximately 10 to 50 mg/L of *sodium* fluoride, as there are 2.2 parts sodium for each 1 part fluoride.

⁵⁸ EPA (2018a).

⁵⁹ EPA (1998b), p. 1.

⁶⁰ Teng et al. (2018).

⁶¹ For example, Güner et al. (2016); Liu et al. (2011); Yang et al. (2018a); Zhang et al. (2015a).

⁶² EPA (1998a), p. 38.

maternal toxicity (i.e., 20% or more reduction in weight gain during gestation and lactation), interpretation of developmental effects may be confounded.”⁶³ The fact that there is some effect on body weight, therefore, does not, by itself, negate a direct neurotoxic effect; the effect on body weight must be relatively large (i.e., >20%). While some of the animal studies on fluoride do show some body weight reductions, many do *not*—particularly at the lowest doses causing the effects. Systemic toxicity is thus an unlikely explanation of the neurotoxic effects reported.

2. NTP Systematic Review for Australian Government (2015)

70. In 2015, the National Toxicology Program (NTP) completed a systematic review of the animal literature on fluoride neurotoxicity and submitted a report to the Australian government.⁶⁴ The NTP limited its review to studies that have measured learning, memory, and other behavioral effects.⁶⁵ In total, the NTP identified 44 studies of learning and memory, 14 of which were excluded due to risk of bias from lack of randomization, lack of blinding at outcome assessment, or other design deficiencies.⁶⁶ From the remaining 30 studies, NTP concluded that there was “a moderate level-of-evidence for a pattern of findings suggestive of an effect on learning and memory in rats treated during development or adulthood.”⁶⁷ Moderate level of evidence is the second highest level of evidence under NTP’s 5-grade classification criteria.⁶⁸

⁶³ EPA (1998a), p. 46.

⁶⁴ NTP (2015a).

⁶⁵ NTP (2015a), pp. 1, 28.

⁶⁶ In addition to PubMed, NTP searched several additional databases. NTP (2015a), p. 1.

⁶⁷ NTP (2015a), p. 1.

⁶⁸ NTP (2015a), p. 11. Under NTP’s Hazard Identification Scheme, a chemical that has a moderate level of evidence of neurotoxicity in animals and a moderate level of evidence of neurotoxicity in humans is a “presumed” neurotoxicant (NTP 2015b, p. 67, Figure 8).

3. NTP Systematic Review (2016)

71. In 2016, the NTP published an updated version of its systematic review.⁶⁹ In the updated review, NTP identified an additional four studies on learning and memory, two of which were excluded for bias, resulting in a total of 32 studies for its analysis.⁷⁰ NTP maintained its conclusion that the animal evidence is “suggestive” that fluoride impairs learning and memory, but downgraded its confidence in the developmental studies to “low.”⁷¹ NTP had less confidence in the developmental studies due to their general failure to control for litter effects, as well as the relatively few developmental studies that used fluoride concentrations lower than 25 mg/L in drinking water.⁷²

72. The NTP identified several common methodological limitations with the learning and memory studies, including failure to rule out fluoride-induced motor effects as the cause of the apparent cognitive deficits; failure to control for “litter effects” in the developmental studies; lack of blinding; and lack of reported information on the study conditions, including the purity of the fluoride added to the water and the concentrations of fluoride in the rodent chow.

73. In contrast to NTP’s 2015 report, the 2016 report considered the absence of animal studies using 0.7 mg/L (the current recommended fluoride concentration for human drinking water⁷³) to be an important limitation in the research in terms of its relevance to human exposure levels.⁷⁴

⁶⁹ NTP (2016).

⁷¹ NTP (2016), p. vii.

⁷² NTP (2016), p. 57.

⁷³ USDHHS (2015).

⁷⁴ NTP (2016), pp. 55, 58.

4. Assessment of NTP's Review

74. The suggestion by NTP that rodent studies should use fluoride concentrations of 0.7 mg/L in order to be relevant to human exposures is at odds with EPA's approach to risk assessment.⁷⁵ As I discuss later, humans are considered much more sensitive to toxicants than are rats and mice, and the EPA has developed procedures to account for this increased sensitivity. The net effect of EPA's procedures is that what might initially seem to be a "high" dose in animal studies may be very relevant to assessing risk in humans at lower doses.

75. By limiting its review to studies investigating learning and memory, the NTP did not consider the much larger number of studies that have investigated neuroanatomical and neurochemical effects, endpoints that are more sensitive and also potentially less susceptible to bias associated with outcome assessment.

76. The NTP correctly identified a number of methodological limitations in the learning/memory studies. The lack of blinding in some studies, for example, does create some uncertainty because lack of blinding can bias results in the direction of the anticipated effect.⁷⁶ Some of the limitations, however, would not be expected to skew the results in a consistent direction across laboratories (e.g., lack of information on the purity of the fluoride compounds). Similarly, litter effects can produce false negatives as well as false positives, and can both inflate and deflate the true effect size.⁷⁷ The impact of these limitations on the reported results is thus unclear, particularly when considering that the studies also have limitations that will make it harder

⁷⁵ The principal author of the NTP study, Kristina Thayer, testified at her deposition that she is no longer comfortable with the assumption of a 1-to-1 equivalence between fluoride exposures in animals and humans; Thayer testified that she would approach the issue differently today, with greater attention to interspecies differences in toxicokinetics and toxicodynamics. (Thayer Deposition at 151:9-152:3, 302:21-303:23). These issues are discussed further below.

⁷⁶ Holman et al. (2015).

⁷⁷ Zorrilla (1997), p. 144; Lazic and Essioux (2013), p. 3.

to detect effects, including the absence of chronic studies and the absence of studies investigating neonatal exposures that are comparable to formula-feeding exposures in human infants, as discussed further below.

77. Although the NTP expressed concern about the difficulty of distinguishing fluoride's effects on learning/memory from its effects on the motor/sensory system, each of these effects is neurotoxic and a matter of concern.

5. Developmental Studies Published Since the NTP Review

78. Subsequent to the NTP's review, 11 additional developmental studies have reported learning and memory outcomes.⁷⁸ Ten of these studies found deficits in the fluoride-treated groups. Notably, the Bartos et al. studies, which controlled for litter effects, found impairments in learning and memory at a fluoride concentration of just 5 mg/L. I will discuss these studies further in the Quantitative Dose Response section below.

6. McPherson (2018) and Other "No Effect" Studies

79. McPherson et al. (2018) is the one developmental study published since the NTP review that did not find clear adverse effects on learning and memory, although it did find a significant increase in pain sensitivity (a neurotoxic effect).

80. There are several features of the McPherson study that may help to explain the absence of a clear effect on learning and memory. First, unlike the overwhelming majority of previous studies on fluoride neurotoxicity, the McPherson study used Long Evans Hooded rats, which some have suggested may have lower sensitivity to fluoride than other strains.⁷⁹ To date,

⁷⁸ Bartos et al. (2018; 2019); Chen et al. (2018a); Cui et al. (2017); Ge et al. (2018); McPherson et al. (2018); Sun et al. (2018); Wang et al. (2018a); Zhao et al. (2019); Zhu et al. (2017); Zhou et al. (2019).

⁷⁹ Elliott (1967).

three studies⁸⁰ have examined the effect of fluoride on learning in Long Evans rats, and all three have failed to find an effect.⁸¹

81. Second, in contrast to most of the other developmental studies, McPherson et al. did not start the exposure until the 6th day of gestation.⁸² As pregnancy in rats lasts approximately 21 days, any effects due to exposures early in, or preceding, the pregnancy may not have been detected by McPherson's study design.

82. Third, the offspring in the McPherson study had virtually no fluoride exposure during the neonatal period because the rat pups were breastfed during the pre-weaning period. This is important because the fluoride content of breast milk in rats (as with other mammals, including humans) is negligible, even when the mother is consuming large quantities of fluoride.⁸³ The rats in the McPherson study thus missed a potentially key period of vulnerability (early infancy)—an important limitation given the widespread use of infant formula among human neonates.⁸⁴

83. In addition to the McPherson study, three other studies (with weaker study designs) reported no neurotoxic effects from fluoride exposure.⁸⁵ These three studies include Whitford et al. and Pulungan et al. which started with adult animals, and an unusual study by Jia et al. which started at gestational day 9. All or part of the gestational period was thus missed in each of these studies.

⁸⁰ Elliott (1967); Varner et al. (1994); McPherson et al. (2018).

⁸¹ The plausibility of strain-specific differences between Long Evans and other rats is supported by other research which has found that Long Evans Hooded rats have different sensitivities to teratogenic substances in utero than Sprague-Dawley rats (Kang et al. 1986).

⁸² McPherson et al. (2018).

⁸³ Fluoride concentrations in mammalian milk are very low in comparison to the mother's fluoride intake, even when the mother's fluoride intake is quite high (NRC 2006, pp. 33, 36; Drinkard et al. 1985).

⁸⁴ This limitation is not unique to the McPherson study, as all other developmental studies on fluoride have failed to supplement the pup's exposure during the breastfeeding stage.

⁸⁵ Whitford et al. (2009); Pulungan et al. (2018); Jia et al. (2019).

84. According to the *Guidelines*, “To judge that an agent is unlikely to pose a hazard for neurotoxicity, the minimum evidence would include data from a host of endpoints that revealed no neurotoxic effects.”⁸⁶ This evidence does not exist for fluoride. To the contrary, almost all studies, including McPherson et al. (2018), have reported adverse effects on at least one of the endpoints measured.

D. Other Considerations

1. Dose Response

85. The *Guidelines* recognize that “determining a hazard often depends on whether a dose-response relationship is present,”⁸⁷ and thus “dose-response evaluation is a critical part of the qualitative characterization of a chemical’s potential to produce neurotoxicity.”⁸⁸ Because “human studies covering a range of exposures are rarely available,” the *Guidelines* state that the dose-response evaluation will typically be limited to animal data.⁸⁹

86. In contrast to the chemicals that EPA has evaluated under the *Guidelines*, there is abundant dose-response data for fluoride from *human* studies. Most importantly, the ELEMENT and MIREC birth cohort studies have found linear dose-response relationships between maternal urinary fluoride and IQ in the offspring.⁹⁰ The linearity of the dose-response relationships in these studies was not simply assumed—it was scrutinized through several methods, which I understand Drs. Hu and Lanphear will be explaining as part of their testimony.

87. Dose-response trends have also been observed in cross-sectional studies as a function of childhood urine and serum fluoride levels, although these are inherently less certain.⁹¹

⁸⁶ EPA (1998a), pp. 55-56.

⁸⁷ EPA (1998a), p. 2.

⁸⁸ EPA (1998a), p. 50.

⁸⁹ EPA (1998a), p. 50.

⁹⁰ Bashash et al. (2017; 2018); Green et al. (2019).

⁹¹ Cui et al. (2018); Ding et al. (2011); Xiang et al. (2011); Zhang et al. (2015b).

An important limitation with dose-response data from cross-sectional studies is that the exposures are tested after the effect (reduction in IQ) has occurred. The data, however, are not without value, as current exposures can be reflective of developmental exposures in areas with stable populations and stable water fluoride concentrations. In the Zhang study, for example, most of the children had been living in the same household and drinking from the same wells since birth.⁹²

88. In addition to dose-response data from human studies, there is also considerable dose-response data from animal studies. A prerequisite for dose-response analysis in animal studies is that there be multiple treatment groups with different exposures to the test substance. Many of the animal studies on fluoride have used multiple treatment doses, and thereby permit evaluation of dose response. Of the studies published since the NRC review (summarized in Table A-1), 1 used four treatment doses, 17 used three treatment doses, and 16 used two treatment doses (in addition to the control groups). Of these 34 studies, 30 show visually apparent dose-response trends for at least one of the effects being investigated.

2. Neuroendocrine Effects

89. EPA's *Guidelines* recognize the relevance of a chemical's ability to alter the function of the thyroid gland.⁹³ According to the *Guidelines*, "the development of the nervous system is intimately associated with the presence of circulating hormones such as thyroid hormone."⁹⁴ A thyroid disturbance during a specific developmental period may cause a "nervous system deficit, which could include cognitive dysfunction, altered neurological development, or visual deficits, [depending] on the severity of the thyroid disturbance and the specific developmental period when exposure to the chemical occurred."⁹⁵ Elsewhere, EPA has recognized

⁹² Zhang et al. (2015b), p. 4.

⁹³ EPA (1998a), p. 50.

⁹⁴ EPA (1998a), p. 50.

⁹⁵ EPA (1998a), p. 50.

that “thyroid hormones are essential for normal brain development in humans and that hypothyroidism during fetal and early neonatal life may have profound adverse effects on the developing brain.”⁹⁶

90. Thyroid toxicity may be a significant mechanism by which fluoride affects neurodevelopment. In 2006, the NRC had enough information to conclude that fluoride is an “endocrine disrupter” which may lower thyroid function.⁹⁷ Sodium fluoride was once prescribed as a therapeutic agent for *lowering* thyroid activity in cases of *hyperthyroidism*.⁹⁸ The NRC reported that fluoride can lower thyroid function at estimated average intakes of 0.05-0.13 mg/kg/day in humans with adequate iodine intake, and at estimated average intakes as low as 0.01 to 0.03 mg/kg/day in individuals with iodine deficiency.⁹⁹ Put differently, fluoride affects thyroid function at lower doses in people with iodine deficiency than in those with optimal intake of iodine.

91. Epidemiological research published subsequent to the NRC’s report is consistent with and further supports NRC’s findings. In 2018, Malin et al. reported a relationship between urinary fluoride and elevated TSH (thyroid stimulating hormone) among iodine-deficient adults in Canada, but not in the general population as a whole (excluding those with known thyroid disease and excluding pregnant individuals).¹⁰⁰ Elevated TSH is indicative of a decrease in thyroid function. Ten percent of women of child-bearing age in the US are iodine deficient.¹⁰¹

⁹⁶ EPA (2008a), p. 40, citing Morreale de Escobar et al. (2000) and Haddow et al (1999). See also EPA (2008b), p. 54, citing Morreale de Escobar et al. (2000). EPA’s Science Advisory Board in 2013 found that “the most sensitive life stages are the fetus, neonates and infants because these are the stages when thyroid-dependent brain development occurs” (EPA 2013b, cover letter, p. 2).

⁹⁷ NRC (2006), pp. 262-263.

⁹⁸ Galletti and Joyet (1958). Consistent with this thyroid use (i.e., lowering thyroid function), fluoride exposure has been associated with hypothyroidism in animal and human studies (Hillman et al. 1979; Peckham et al. 2015; Yang et al. 2019).

⁹⁹ NRC (2006), pp. 262-263.

¹⁰⁰ Malin et al. (2018). Barberio et al. (2017) found no association between fluoride exposure and thyroid status, but the iodine-deficient part of the population was not specifically addressed.

92. In 2015, a nationwide study from England reported a significant association between water fluoridation and increased prevalence of hypothyroidism.¹⁰²

3. Toxicokinetics

93. Under the *Guidelines*, consideration should be given to the toxicokinetics of the chemical with “particular importance” given to the chemical’s capacity to get through the blood-brain barrier.¹⁰³ The permeability of the blood brain barrier is particularly important when a chemical, such as fluoride, is able to make it through the placenta. Studies in humans have repeatedly demonstrated that fluoride crosses the placenta and reaches the fetus,¹⁰⁴ and thus it is generally accepted that “fluoride readily crosses the placenta.”¹⁰⁵ In general, measured concentrations of fluoride in umbilical cord blood and in blood of neonates are similar to concentrations in maternal blood.¹⁰⁶ In short, the fluoride that a mother ingests will cause exposure to the fetus.

94. Fluoride is also known to cross the blood-brain barrier,¹⁰⁷ and passage of fluoride into the brain can be expected to be higher during the fetal and neonatal life stages when the blood brain barrier is not yet fully developed.¹⁰⁸ As the EPA has recognized, “Because the blood-brain barrier limits the passage of substances from blood to brain, in its absence, toxic agents can freely enter the developing brain.”¹⁰⁹ Consistent with EPA’s observation, the recent rat study by

¹⁰⁹ EPA (2009b), p. 58.

McPherson et al. found sharply elevated concentrations of fluoride in the brain following prenatal exposure.¹¹⁰

4. Mode of Action

95. EPA's *Guidelines* recognize that hazard identification is strengthened by, but not dependent upon, an identifiable mechanism by which the chemical can exert neurotoxic effects.¹¹¹ For most of the chemicals for which EPA has established RfDs pursuant to the *Guidelines*, the mode of action has not been known (see Table 1). As noted recently by the NAS, "solid conclusions about causality can be drawn without mechanistic information, for example, when there is strong and consistent evidence from animal or epidemiology studies."¹¹² The NAS added that "mechanistic frameworks today could probably be completed for only a few chemicals."¹¹³

96. Several plausible mechanisms—both indirect and direct—have been identified that could help explain the neurotoxicity of fluoride.

97. *Indirect Mechanisms:* Depression of thyroid function is likely a principal indirect mechanism and could account for some of the neurotoxic effects reported in the literature. A thyroid mechanism is particularly plausible as a cause of IQ loss among offspring born to women with suboptimal iodine intakes.

98. *Direct Mechanisms* A recent study by Zhao et al. provides *in vitro*, *in vivo*, and epidemiological data that, together, suggest that disturbances in hippocampal mitochondrial dynamics (marked by fission inhibition and fusion promotion) play an important role in fluoride-induced cognitive loss.¹¹⁴ The hippocampus is an important region in the brain for learning and

¹¹⁰ McPherson et al. (2018).

¹¹⁴ Zhao et al. 2019.

memory, and many of the studies investigating the neuroanatomical and neurochemical effects of fluoride exposure have identified adverse effects in this region (see Table A-1). Other potential modes of action have also been identified, including signaling disruption, oxidative stress, and selective reductions in nicotinic receptors.¹¹⁵

5. In Vitro Studies

99. EPA's *Guidelines* also call for consideration of *in vitro* data. While positive *in vitro* data are not sufficient, by themselves, to demonstrate a neurotoxic hazard in humans, the existence of such data helps enhance the reliability of *in vivo* data.¹¹⁶

100. Fluoride's ability to damage brain cells has been documented in *in vitro* experiments. While most of the *in vitro* studies have used high concentrations that are unlikely to be present in the human brain, several studies have examined environmentally realistic fluoride concentrations. Gao et al. found increased lipid peroxidation and reduced $\alpha 7$ nicotinic acetylcholine receptors in brain cells at fluoride concentrations (i.e., 9.5 parts per billion) that are commonly found in the blood of people living in fluoridated areas.¹¹⁷ Increases in markers of neuroinflammation have also been found at low concentrations.¹¹⁸ Under the *Guidelines*, these data do not demonstrate a hazard in humans, but they do enhance the reliability of the animal studies, as similar effects have been reported in fluoride-treated rodents.¹¹⁹

6. Validity of the Database

101. Under the *Guidelines*, the validity of the database should be evaluated by assessing

¹¹⁵ Bartos et al. (2018); Chen et al. (2003; 2018a); Gao et al. (2008); Liu et al. (2010); Long et al. (2002); Shan et al. (2004); Zhang (2017b); Zhu et al. (2017).

¹¹⁹ Bartos et al. (2018); Dong et al. (2015); Yang et al. (2018a); Yan et al. (2016); Zhao et al. (2019).

the content validity, construct validity, concurrent validity, and predictive validity of the data.¹²⁰

102. *Content validity* addresses “whether the effects result from exposure.”¹²¹ This factor weighs decisively in favor of a neurotoxicity hazard determination for fluoride. The NRC concluded that fluoride interferes with the brain,¹²² and the evidence has gotten stronger since. Kristina Thayer, the Director of EPA’s IRIS Division, has explained that “experimental animal studies are designed to let you draw causal inferences,” and that the animal studies show that fluoride damages the brain at some level of exposure.¹²³ Further, while the human cross-sectional studies are limited in their ability to produce causal inferences, the *Guidelines* provide that prospective cohort studies permit “direct estimates of risk attributable to a particular exposure.”¹²⁴

103. *Construct validity* addresses whether the neurologic effects that have been observed “are adverse or toxicologically significant.”¹²⁵ This factor is satisfied in the fluoride database. Animal studies have linked fluoride to learning and memory deficits, which are an adverse effect upon which EPA has established reference doses for other neurotoxicants (e.g., BDE-153).¹²⁶ Further, the human epidemiological data have linked fluoride with IQ detriments, including an approximate 5 to 6 point drop in IQ as maternal urinary fluoride increased from 0 to 1 mg/L.¹²⁷ EPA has recognized that a loss of a single IQ point is associated with a loss in lifetime earnings,¹²⁸ and EPA’s Clean Air Science Advisory Council has stated that “a population loss of 1-2 IQ points

¹²⁸ EPA (2008e), p. 5-28.

is highly significant from a public health perspective” and should be prevented in 99.5% of the population.¹²⁹

104. *Concurrent Validity* addresses “whether there are correlative measures among behavioral, physiological, neurochemical, and morphological endpoints.¹³⁰ Studies have correlated fluoride’s cognitive effects in animals with various neurochemical and neuroanatomical changes,¹³¹ and a few studies have correlated fluoride-associated cognitive loss in humans with increased TSH and alterations in mitochondrial dynamics.¹³² For example, Zhao et al.¹³³ reported lower circulating levels of a mitochondrial protein (fission-related protein-1, Fis1) in children from high fluoride areas (compared with children in low fluoride areas), and higher circulating levels of a second mitochondrial protein (mitofusin-2, Mfn2) in the same children. The levels of circulating Fis1 were positively associated with children's IQ scores, while the levels of circulating Mfn2 were negatively associated with the IQ scores. In addition, several plausible mechanisms of fluoride neurotoxicity have been described (discussed above).

105. *Predictive validity* addresses “whether the effects are predictive of what will happen under various conditions.”¹³⁴ The condition of perhaps greatest interest with respect to prediction of fluoride neurotoxicity is exposure during the prenatal period. Studies in both animals and humans have, with one exception,¹³⁵ reported neurologic effects following prenatal exposure. The database, therefore, does have some degree of predictive validity, although further research remains necessary to determine to what extent other conditions (e.g., nutrition, genetics, neonatal

¹³⁵ McPherson et al. (2018).

exposure, and kidney function) may modify or predict outcomes. Exposure during the early postnatal period also requires further research.

7. Data Gaps

106. EPA's *Guidelines* point to the need to address "significant data gaps."¹³⁶ One of the major data gaps for fluoride is the lack of research on the impact of fluoride during the neonatal and early infancy period. EPA has recognized that the neonatal period represents a critical window of vulnerability to neurotoxicants,¹³⁷ yet most developmental rodent studies do not address neonatal exposures to fluoride (due to exclusive breastfeeding of the rat or mouse pups and absence of gavage exposures). Other data gaps include the absence of long-term animal studies, and the scarcity of epidemiological research into fluoride's neurologic effects in the elderly. Data gaps also remain with respect to how the dose which causes neurologic effects varies across susceptible subsets of the population, including those with nutrient deficiencies, genetic polymorphisms, kidney disease, and the elderly.

E. Conclusion: There Is Sufficient Evidence that Neurotoxicity Is a Hazard of Fluoride

107. The large and substantial body of evidence that now exists for fluoride, from both animal and human studies, satisfies EPA's "sufficient evidence" standard for hazard determination.

108. The *Guidelines* provide that "the minimum evidence sufficient would be data on a single adverse endpoint from a well-conducted study."¹³⁸ The *Guidelines* also recognize that prospective cohort studies are the optimal type of epidemiological study that permit direct

¹³⁶ EPA (1998a), p. 12.

¹³⁷ See for example, EPA (2008a), p. 42.

¹³⁸ EPA (1998a), p. 55.

estimates of risk. The minimum evidence threshold is thus met for fluoride because there is not just one, but *four* high-quality prospective cohort studies that support the endpoint of IQ loss, and another high-quality prospective cohort study that supports the endpoint of inattention.¹³⁹

109. EPA's *Guidelines* also permit consideration of the collective evidence when no study, by itself, is sufficient to permit a hazard determination. This, again, supports a hazard determination for fluoride because the prospective studies are most compelling when viewed in the context of (i) the toxicokinetic data showing that fluoride crosses the placenta and enters the fetal brain; (ii) animal data showing neurochemical and neuroanatomical damage following fluoride exposure; (iii) animal data finding impairments in learning and memory following prenatal exposure to fluoride; (iv) cross-sectional studies consistently finding reductions in IQ in communities with elevated fluoride exposure; (v) *in vitro* studies reporting effects on brain cells at concentrations of fluoride found in the blood of individuals living in fluoridated communities; and (vi) animal and human studies finding that fluoride can depress thyroid function, a known risk factor for neurodevelopmental harm.

110. Based on the collective data—which are far more robust than the data EPA has relied upon for prior hazard determinations—I conclude with a reasonably high degree of confidence that neurotoxicity is a hazard of fluoride exposure.

VI. QUANTITATIVE DOSE RESPONSE

111. If a chemical is identified as posing a neurotoxic hazard, EPA's *Guidelines* call for a quantitative dose-response analysis to determine the reference dose (RfD). The RfD is “an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the

¹³⁹ Bashash et al. (2017; 2018); Green et al. (2019); Till et al. (2020); Valdez-Jiménez et al. (2017).

human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime.”¹⁴⁰

112. In the Quantitative Dose Response analysis, human or animal data are assessed to determine an appropriate “Point of Departure” (POD). As the name implies, the Point of Departure (POD) is the datapoint from which the RfD is ultimately derived. The POD can be one of three types of values: the No Observed Adverse Effect Level (NOAEL), the Lowest Observed Adverse Effect Level (LOAEL) or the Benchmark Dose Level (BMDL). While EPA now has a preference for using BMD, it still uses both the NOAEL and LOAEL approaches in its assessments.

113. The following figure provides a visual illustration of the difference between a NOAEL and LOAEL on a dose-response curve.

A. Basis for Using Animal Data

114. When human data are available, EPA’s preference is to use human data for the Point of Departure.¹⁴¹ In the case of fluoride, the recent prospective cohort studies¹⁴² with individual-level biomonitoring data provide suitable data for this purpose. If one had to choose,

¹⁴⁰ EPA (1998a), p. 57. See also EPA (2009a).

¹⁴¹ EPA (2018a), p. 2-1.

¹⁴² Bashash et al. (2017; 2018); Valdez-Jiménez et al. (2017); Green et al. (2019).

therefore, between deriving the POD for fluoride from the human or animal data, *the choice would clearly be to use the human data*. But this does not mean that the animal data are without value. In EPA's assessment of methylmercury, for example, the EPA derived its RfD from human prospective cohort data, but it also considered what the RfD would be if it were derived from the animal literature.¹⁴³ As the EPA noted, "[i]t is informative to compare RfDs derived from animal studies with those derived from the epidemiological literature."¹⁴⁴ In the case of methylmercury, the animal-based RfD supported the human-based RfD, and EPA cited this as a factor that increased its "confidence" in the assessment.¹⁴⁵

115. In this case, Dr. Philippe Grandjean conducted a dose-response analysis of the prospective cohort data where he derived a BMDL. To avoid duplication of Dr. Grandjean's effort, and to determine whether Dr. Grandjean's BMDL is consistent with potential RfDs derived from the animal data, I focused my assessment on the animal literature.

116. In this assessment, I did not seek to select a single value for the RfD. Instead, I sought to identify the full range of RfDs that can be derived, including the *least* protective. If human exposures exceed RfDs that use non-protective assumptions, there would be greater confidence that a human risk does, in fact, exist.

117. There are several considerations that support the use of animal data to establish an RfD for fluoride. First, EPA has used animal studies as the principal studies for each of the neurotoxicity risk assessments it has thus far conducted under the *Guidelines*. Second, EPA has used impairment in learning and memory in rodents as the adverse effect upon which to base the RfD for other chemicals,¹⁴⁶ thus this is an accepted endpoint to use in deriving an RfD. Third, a

¹⁴³ EPA (2001), pp. 17-18.

¹⁴⁵ EPA (2001), pp. 18-19.

¹⁴⁶ For example, BDE-153 (EPA 2008c, p. 36).

substantial number of animal studies of fluoride neurotoxicity have used 2 or 3 treatment groups (in addition to control groups), and EPA has found this to be sufficient for identifying Points of Departure,¹⁴⁷ including in animal studies with as few as 10 rats per group (2-Hexanone).¹⁴⁸

B. Selecting Points of Departure

118. In the literature review discussed earlier, 37 rodent studies were identified that have investigated fluoride's impact on learning and memory since the NRC report (Table A-2). All but 3 of these studies found adverse effects in the fluoride-treated rodents, including 16 of the 17 studies that investigated prenatal fluoride exposures. Since the prenatal period represents a point of heightened vulnerability to neurotoxicants, the prenatal studies are a logical candidate for the point of departure.

119. To avoid studies at high risk of bias, the three studies that did not specifically mention using a randomization procedure were excluded from further consideration.¹⁴⁹ Further, in order to focus the analysis on those studies best suited for identifying a Point of Departure (POD), four studies that only used one treatment dose were excluded.¹⁵⁰

120. Table 2 and the figures below summarize the 10 prenatal studies that remained for POD consideration. Most of the studies used a similar dosing regimen with 2 or 3 treatment groups and at least 10 rodents per group, which is consistent with several of the principal studies that EPA has used to establish an RfD. The figures show the lowest-observed and no-observed effect levels in each study and help to visually compare the data across studies.

121. Nine of the 10 studies found dose response trends for one or more effects, which

¹⁴⁷ EPA (2000b; 2008a; 2008c; 2008d; 2009b).

¹⁴⁸ EPA (2009b).

¹⁴⁹ Bera et al. (2007); Basha et al. (2011b); Ge et al. (2018).

¹⁵⁰ Niu et al. (2014); Banala and Karnati (2015); Dong et al. (2015); Zhu et al. (2017).

adds confidence to a causative role of the fluoride treatment.¹⁵¹ Six of these studies also provide data on the body weights of the pups, and no bodyweight changes were seen in any of the studies at the lowest concentrations producing the effects.¹⁵² Only one of the six studies found any bodyweight changes among pups in the higher-dose groups.¹⁵³ Of the two studies that reported maternal weight, neither found any changes.¹⁵⁴

122. One limitation with these studies is that only three of them specifically mention controlling for litter effects,¹⁵⁵ which introduces some uncertainty since the failure to control for litter effects can result in false positives, as well as false negatives.¹⁵⁶ While a source of uncertainty, the failure to control for litter effects does not preclude use for risk assessment purposes. As noted earlier, EPA has used studies that do not control for litter effects as the principal studies upon which it has based RfDs for developmental neurotoxicity.¹⁵⁷

¹⁵¹ See for example, Jiang et al. (2014b), Table 3; Cui et al. (2017), Table 3; Chen et al. (2018a), Figure 1d,e; Sun et al. (2018), Tables 2 and 3; Wang et al. (2018a), Figure 4b,c; Zhao et al. (2019), Figure 5e.

¹⁵² Bartos (2018; 2019); Cui et al. (2017); Jiang et al. (2014b); Wang et al. (2018a). The study by McPherson (2018) also showed no changes in bodyweight, although it did not find effects on learning/memory.

¹⁵³ Jiang (2014b) found reduced body weight gain among the pups in the 23 mg/L and 45 mg/L groups.

Jiang et al. (2014b)	Rats, Sprague- Dawley	Prenatal ^b + 2 months	11, 23, 45	12	11	None	11	None

^a Treatment groups in addition to the control group.^b Exposure of the mother began before pregnancy.^c Animals were given 0, 10, or 20 mg/L fluoride in drinking water, plus 3.24 ppm fluoride in feed. An additional control group had 0 mg/L fluoride in drinking water plus 20.5 ppm fluoride in feed (McPherson et al. 2018).

123. Based on the dose-response data from these studies, the following values could be used as the Point of Departure.

124. **LOAEL of 5 mg/L:** The lowest observed adverse effect levels in the studies were fluoride concentrations of 4.5 and 5 mg/L. Of the six studies that used this concentration, three

found adverse effects on learning,¹⁵⁸ and two of the other three studies, which did not find effects on learning, *did find alterations in the brain*.¹⁵⁹ Two of the three studies reporting effects on learning at 5 mg/L controlled for litter effects, which suggests that the failure to control for litter effects is unlikely to explain the reported effects at this concentration.¹⁶⁰ A 5 mg/L LOAEL was selected, therefore, as one of the Points of Departure (PODs) for learning impairment from prenatal fluoride exposure.

125. **LOAEL of 23 mg/L**: Seven of the 10 studies used 23 mg/L as one of the treatment doses, and all 7 of these studies found impaired performance on the cognitive tests, with 6 of the 7 studies finding changes in the brain as well. 23 mg/L appears, therefore, to be a reliable “Observed Adverse Effect Level,” particularly in light of the six studies (discussed above) which found adverse effects at < 5 mg/L. Although not the *lowest* observed effect level, it is assumed to be one for purposes of this Point of Departure.

126. **LOAEL of 45 mg/L**: As can be seen in the above figures, 45 mg/L is clearly an “observed adverse effect level,” just as it has been in many other animal studies on fluoride neurotoxicity. It would be difficult to justify selecting 45 mg/L as the LOAEL because it is the *highest* observed adverse effect level in this group of studies, not the *lowest*. Nevertheless, for purposes of capturing the broadest possible range of RfDs that can be derived from the animal literature, a 45 mg/L LOAEL was selected as one of the Points of Departure.

¹⁵⁸ Cui et al. (2017); Bartos et al. (2018; 2019). In the Chen study (which had only six rats per group), there is some indication of an effect on learning in the 4.5 mg/L group, albeit not statistically significant (Chen et al. 2018a, Figure 1).

¹⁵⁹ Chen et al. (2018a); Zhao et al. (2019). Other studies have also found alterations in the brain at ≤ 5 mg/L, including Liu et al. (2010; 2011); Zhang et al. (2015a); Niu et al. (2018a); Varner et al. (1998); and Yu et al. (2019).

¹⁶⁰ Bartos et al. (2018; 2019).

127. **NOAEL of 11 mg/L:** Four of the prenatal studies used 10 or 11 mg/L for the low-dose group.¹⁶¹ The two studies of mice failed to find a significant effect on learning at this level,¹⁶² and, as such, 11 mg/L could be selected as a NOAEL. The fact that the two studies that did not find effects at 11 mg/L found them at higher concentrations (23 and 45 mg/L) would be a factor weighing in favor of this choice, as the animal models were sensitive enough to find an effect. It bears considering, however, that the two studies finding no effects on learning at 11 mg/L did find alterations in the brain at this level,¹⁶³ which is consistent with 11 mg/L being a LOAEL, rather than a NOAEL. However, for purposes of reflecting the spectrum of RfDs that can be derived from the animal literature, 11 mg/L was treated as a NOAEL for one of the PODs.

128. **NOAEL of 20 mg/L:** The highest possible NOAEL that can be selected from these prenatal studies is the 20 mg/L no-effect finding from McPherson et al.¹⁶⁴ As discussed earlier, there are limitations with the McPherson study that may have made it less sensitive to detecting an effect, including strain of rat used and lack of first trimester exposure. Further, the study did find an adverse neurotoxic effect in the 20 mg/L group (i.e., increased pain sensitivity), and, as such, 20 mg/L is not a true NOAEL in the study. Nevertheless, for the purpose of illustrating the upper-bound range of RfDs that can be derived from the animal literature, a 20 mg/L NOAEL will be treated as a POD for the analysis.

C. Conversion of POD Concentrations (mg/L) to Doses (mg/kg/day)

129. Reference Doses (RfDs) are expressed in terms of dose (i.e., milligrams per kilogram of bodyweight, or mg/kg/day), not in terms of water concentration. To calculate RfDs from the Points of Departure, therefore, the unit of measurement (i.e., water fluoride concentration)

¹⁶¹ Wang et al. (2018a); Sun et al. (2018); McPherson et al. (2018); Jiang et al. (2014b).

¹⁶² Sun et al. (2018); Wang et al. (2018a).

¹⁶³ Sun et al. (2018); Wang et al. (2018a).

¹⁶⁴ McPherson et al. (2018).

needs to be converted into a dosage metric.

130. The NTP's 2016 review provides data that facilitate this analysis.¹⁶⁵ In its review, the NTP estimated the doses for dozens of rodent studies by using EPA's default water consumption rates and body weight data for the species, strain, and sex of the animals studied.¹⁶⁶ A review of NTP's data shows that the average ratio of fluoride concentration (mg/L) to intake rate or dose (mg/kg/day) is 6.8, and that this ratio is generally higher for rats (typically 6 to 10) than for mice (typically 3.8 to 5). For purposes of this analysis, the low end of this range was chosen for each species (6 for rats, 3.8 for mice). The practical effect of selecting the low-end of this range, is that the estimated doses will likely *overestimate* the actual dose, and thereby *inflate* the RfDs derived from these Points of Departure.¹⁶⁷ The net result of this non-conservative approach will be RfDs that are *less* protective of human health.

D. Selecting the Uncertainty Factors

131. Consistent with EPA's standard risk assessment procedures,¹⁶⁸ the *Guidelines* provide that "uncertainty factors" (UFs) should be applied to the point of departure (POD) to ensure that the resulting RfD is protective of health.¹⁶⁹

132. Uncertainty factors are applied to account for expected variations in susceptibility among humans (*intraspecies* variability, or UF_H), expected differences in susceptibility between animals and humans (*interspecies* variability, or UF_A), and, where applicable, differences in the

¹⁶⁵ NTP (2016), Appendix 19.

¹⁶⁶ NTP (2016), p. 118.

¹⁶⁷ For example, using this method gives an intake rate of 0.83 mg/kg/day for rats for the 5 mg/L fluoride concentration (Table 5). However, Bartos et al. (2018; 2019) give an estimate of 0.6 mg/kg/day for their rats at this fluoride concentration. Using the same approach described below with Table 5 for a LOAEL of 5 mg/L, equivalent to an intake rate of 0.6 mg/kg/day, gives an RfD of 0.0005, compared with 0.0007 in Table 5.

¹⁶⁸ EPA (2018a), pp. xvii-xxiv.

¹⁶⁹ EPA (1998a), pp. 58-59.

length of exposure between the study and human conditions (subchronic to chronic, or UF_S), research gaps in the overall database (database deficiency, UF_D), and converting from a LOAEL to a NOAEL.¹⁷⁰ These uncertainty factors are “typically multiples of 10,” although they can be reduced to factors of 3 or 1 if warranted by available information.^{171,172}

1. Intraspecies Variability (UF_H)

133. EPA recognizes that susceptibility to toxic substances is not uniform across the human population, and that due to differences in *toxicokinetics* and/or *toxicodynamics* some subsets of the population will be more vulnerable to harm than others.¹⁷³

134. *Toxicokinetics* refers to the “processes which determine the extent and duration of exposure of the target organ or site of toxicity to the active chemical species,” while *toxicodynamics* refers to the “processes involved in the translation of such exposure of the target organ or site of action into the generation of a toxic effect.”¹⁷⁴ Put more simply, toxicokinetics governs how much of the chemical gets to the target site (i.e., access), while toxicodynamics governs how much of the chemical is necessary at the target site to cause the adverse effect (i.e., sensitivity).

135. If there are no chemical-specific data on toxicokinetics and toxicodynamics, EPA uses a default UF_H of 10.¹⁷⁵ This default factor of 10 is “considered to be appropriate in the absence of convincing data to the contrary.”¹⁷⁶ Consistent with this, EPA has used a UF_H of 10 in each of

¹⁷⁰ EPA (1998a), p. 59; EPA (2018a), p. xxii; EPA (2016), pp. xix-xx.

¹⁷¹ EPA (1998a), p. 59; EPA (2018a), p. xxii; EPA (2016), p. xix.

¹⁷² As discussed by Martin et al. (2013), default uncertainty factors, while sometimes viewed as overly protective, do not represent worst-case situations and cannot be safely assumed to be adequately protective of the most exposed individuals or the most susceptible individuals, nor can they be safely assumed to be protective for effects of mixtures of chemicals.

¹⁷³ EPA (2011b), p. 14; EPA (2016), p. 2-15; EPA (2018a), p. 2-12.

¹⁷⁴ Renwick (1993), p. 276.

¹⁷⁵ EPA (2018a), pp. 2-12, 2-13.

¹⁷⁶ EPA (2013a), p. 5-17.

the nine risk assessments where it has established an RfD or RfC pursuant to the *Guidelines* (Table 3).

136. In the case of fluoride, there is evidence that affirmatively demonstrates substantial variability in how humans respond to fluoride, including differences in retention (toxicokinetics) and differences in response (toxicodynamics). These data are discussed below in the Risk Characterization. While the magnitude of this variability is difficult to quantify, the data *support* the need for an uncertainty factor as opposed to providing “convincing data” *against* one. Accordingly, pursuant to standard EPA procedure, a value of 10 for UF_H was assigned.

Table 3. Summary of RfDs or RfCs developed in compliance with EPA's Guidelines for Neurotoxicity Risk Assessment.

Chemical	LOAEL	NOAEL	Uncertainty Factors					RfD or RfC ^a	Reference
			UF _H	UF _A	UF _S	UF _D	Composite		
BDE-47	10.5 mg/kg	0.7 mg/kg	10	10	3	10	3000	0.1 µg/kg/day	EPA (2008a)
BDE-99	0.8 mg/kg	0.4 mg/kg	10	10	3	10	3000	0.1 µg/kg/day	EPA (2008b)
BDE-153	0.9 mg/kg	0.45 mg/kg	10	10	3	10	3000	0.2 µg/kg/day	EPA (2008c)
BDE-209	20.1 mg/kg	2.22 mg/kg	10	10	3	1	300	7 µg/kg/day	EPA (2008d)
Chlorine Dioxide and Chlorite	6 mg/kg/day	3 mg/kg/day	10	10	1	1	100	0.03 mg/kg/day	EPA (2000b)
2-Hexanone	143 mg/kg/day	Not observed	10	10	1	10	1000	0.005 mg/kg/day	EPA (2009b)
Methanol	1000 ppm (1310 mg/m ³)	500 ppm (655 mg/m ³)	10	3	1	3	100	20 mg/m ³	EPA (2013a)

^a Where EPA established both an RfD (mg/kg/day) and an RfC (mg/m³) for a chemical, the RfD is presented.

Table 4. Comparison of BW^{1/1} and BW^{3/4} in estimating oral exposure in humans from a 10 mg/kg exposure to rats, mice, and a dog.^a

Absolute animal intake or administered dose	Species	BW(h)/BW(a)	Scaling = BW ^{1/1}		Scaling = BW ^{3/4}	
			BW scaling factor	BW scaled human intake or oral dose (mg/kg)	BW scaling factor	BW scaled human intake or oral dose (mg/kg)
0.25 mg / 0.025 kg	Mouse	70 / 0.025 = 2800	2800 ^{1/1} = 2800	(2800 × 0.25 mg = 700 mg) 700 mg / 70 kg = 10 mg/kg	2800 ^{3/4} = 385	(385 × 0.25 mg = 96 mg) 96 mg / 70 kg = 1.4 mg/kg
2.5 mg / 0.25 kg	Rat	70 / 0.25 = 280	280 ^{1/1} = 280	(280 × 2.5 mg = 700 mg) 700 mg / 70 kg = 10 mg/kg	280 ^{3/4} = 68	(68 × 2.5 mg = 170 mg) 170 mg / 70 kg = 2.4 mg/kg
120 mg / 12 kg	Dog	70 / 12 = 5.8	5.8 ^{1/1} = 5.8	(5.8 × 120 mg = 700 mg) 700 mg / 70 kg = 10 mg/kg	5.8 ^{3/4} = 3.7	(3.7 × 120 mg = 444 mg) 444 mg / 70 kg = 6.4 mg/kg

^a Taken from Table A-1 in EPA (2011b), p. 29.

2. Interspecies Variability (UF_A)

137. EPA recognizes that susceptibility to toxic substances can differ across species. As with human-to-human variability, animal-to-human variability is also rooted in principles of toxicokinetics and toxicodynamics.

138. To adjust for differences in toxicokinetics between animals and humans, EPA has developed a hierarchical framework of approaches for ascertaining the “human equivalent dose” (HED) of doses given to animals.¹⁷⁷ EPA’s “optimal” approach for determining the HED is to use a physiologically based toxicokinetic model (PBTk).¹⁷⁸ Where a PBTk model is not available, the “intermediate” approach is to use chemical-specific information that, while falling short of a full PBTk model, provides some reliable guidance.¹⁷⁹ Where there is no reliable chemical-specific information on kinetics, EPA uses a default allometric scaling method.¹⁸⁰

139. Allometric scaling is “scaling of physiological rates or quantities to relative growth and size (mass or volume) of one animal species relative to another species.”¹⁸¹ Under EPA’s recommended method for allometric scaling (BW^{3/4} Method), the HED equates to 24% of the dose given to rats, and 14% of the dose given to mice (see Table 4 above).¹⁸²

140. The BW^{3/4} Method “predominantly addresses factors involved in estimating toxicokinetics, as well as some toxicodynamic factors.”¹⁸³ EPA thus maintains a residual default UF of 3 to allow for residual uncertainty from toxicodynamics, unless there is chemical-specific information available.¹⁸⁴

141. The following factors were considered to account for interspecies differences in both the toxicokinetics and toxicodynamics of fluoride.

142. *Toxicokinetic Considerations:* A full PBTK model has not yet been developed for fluoride that would allow for the calculation of HEDs from doses given to animals. As such, EPA's preferred approach for controlling for interspecies toxicokinetics is not available. By contrast, there is chemical-specific information for fluoride that could support application of EPA's intermediate approach. As discussed by the NRC, rats require higher levels of fluoride in their water to achieve the same level of fluoride in their blood.¹⁸⁵ Dunipace estimated that rats require about 5 times more fluoride in water than humans to reach the same plasma concentration of fluoride,¹⁸⁶ while Den Besten's team has reported a larger margin for mice, with a difference of about a factor of 10.¹⁸⁷ The data from Dunipace and Den Besten support a toxicokinetics adjustment of 5 for rats and 10 for mice, which are slightly *higher* than, but roughly consistent with, the adjustments under the default BW^¾ Method (4 for rats, 7 for mice). The chemical-specific information for fluoride thus supports the general validity of the BW^¾ Method, but would be more protective. The BW^¾ Method, which is roughly consistent with the chemical-specific information, but slightly *less* protective, was selected as the method for the toxicokinetics adjustment.

¹⁸⁵ NRC (2006), pp. 98-99; pp. 442-446, Appendix D; NRC (2009), pp. 88-89.

¹⁸⁶ NRC (2006), pp. 98, 442.

¹⁸⁷ Zhang et al. (2014).

143. *Toxicodynamic Considerations*: It has long been recognized that rodents are less susceptible (i.e., more resistant) to certain toxic effects from fluoride ingestion than are humans.¹⁸⁸ Rats, for example, have been reported to require 10 to 25 times more fluoride than humans to develop dental fluorosis.¹⁸⁹ Differences in toxicokinetics contribute to rodents being less sensitive to fluorosis, but the differences appear larger than would be expected if they were due solely to kinetics. The fluorosis data support the existence of differential toxicodynamics between rodents and humans, but it is unclear if this difference would also apply to neurotoxicity, as this has not yet been the subject of study. Conversely, there are no data to suggest that humans are *more resistant* to fluoride neurotoxicity than animals. In the absence of data, EPA's default uncertainty factor of 3 was selected to account for interspecies differences in toxicodynamic differences.

3. LOAEL to NOAEL

144. When EPA uses a LOAEL from animal data as the Point of Departure, it applies an additional uncertainty factor of 10 to convert the LOAEL into an estimated NOAEL.¹⁹⁰ Consistent with EPA practice, the three LOAEL-based PODs were adjusted by a factor of 10.

4. Composite Uncertainty Factor

145. The "composite" uncertainty factor is the product of all uncertainty factors used in an analysis. The composite uncertainty factor applied here to the NOAEL-based PODs is **30**, which is the same value that EPA has been using in its draft risk evaluations under TSCA.¹⁹¹ The

¹⁸⁸ Roholm (1937), pp. 265, 318; Lehman and Fitzhugh (1954), p. 33; Angmar-Mansson and Whitford (1982), p. 339.

¹⁸⁹ Roholm (1937), pp. 265, 318; Angmar-Mansson and Whitford (1982), p. 339.

¹⁹⁰ EPA (1998a), p. 59.

¹⁹¹ In my expert report, I also calculated alternate RfDs where I applied additional uncertainty factors that EPA uses to account for subchronic animal exposures and deficiencies in the fluoride database (e.g. no data on formula-feeding during the neonatal period). For purposes of simplicity, I have not included those calculations in this declaration.

composite uncertainty factor applied here to the LOAEL-based PODs is **300**, which is on the low-end of the range of the composite uncertainty factors that EPA has used in its neurotoxicity risk assessments (see Table 3 above).

E. RfD Calculations from Animal Data

146. Table 5 summarizes the RfD calculations for each of the five Points of Departure (POD) listed above. The RfDs range from 0.0007 to 0.006 mg/kg/day for the LOAEL-based PODs, and 0.01 to 0.03 mg/kg/day for the NOAEL-based PODs. The least protective RfD that can be derived from the literature in a manner consistent with EPA practice is thus **0.03 mg/kg/day**.

Table 5. Calculation of the RfD from the selected Points of Departure (POD), based on the studies summarized in Table 2.

A Observation	B Intake rate	C POD _{HED}	D NOAEL	E UF _H = 10	F UF _A = 3	G RfD
LOAEL or NOAEL from Table 6 mg/L	Column A / 6 (rats) or 3.8 (mice) mg/kg/day	Column B × 0.24 (rats) or 0.14 (mice) mg/kg/day	Column C / 10 (LOAEL) or 1 (NOAEL) mg/kg/day	Column D / 10 mg/kg/day	Column E / 3 mg/kg/day	Column F mg/kg/day
5 mg/L, LOAEL (rats)	0.83	0.20	0.020	0.0020	0.00067	0.0007
23 mg/L, LOAEL (rats)	3.8	0.91	0.091	0.0091	0.0030	0.003
45 mg/L, LOAEL (rats)	7.5	1.8	0.18	0.018	0.0060	0.006
11 mg/L, NOAEL (mice)	2.9	0.41	0.41	0.041	0.014	0.01
20 mg/L, NOAEL (rats)	3.3	0.79	0.79	0.079	0.026	0.03

Column A: The observed LOAEL or NOAEL from Table 2.

Column B: The observed LOAEL or NOAEL converted from mg/L to an intake rate (dose) in mg/kg/day. For rats, the LOAEL or NOAEL is divided by 6; for mice, the NOAEL is divided by 3.8 (see explanation in text).

Column C: The intake rate for rats or mice converted to a human equivalent dose (HED) using the BW^{3/4} method (see explanation in text). The HED = 24% of the intake rate for rats or 14% of the intake rate for mice.

Column D: NOAEL as already obtained (NOAEL / 1) or as estimated from a LOAEL (LOAEL / 10).

Column E: The estimated NOAEL after application of an intraspecies uncertainty factor (UF_H), where UF_H = 10. The NOAEL from Column D is divided by UF_H (i.e., NOAEL / 10).

Column F: The estimated NOAEL after application of an additional uncertainty factor for interspecies variability (UF_A), where UF_A = 10. The adjusted NOAEL from Column E is divided by UF_A (i.e., NOAEL / 3).

Column G: The value of the Reference Dose (RfD) obtained with only UF_H and UF_A. RfD = the NOAEL value in Column F, rounded to 1 significant digit.

VII. EXPOSURE ASSESSMENT

147. The only condition of use at issue in this case, as I understand it, is the addition of fluoridation chemicals to drinking water. Because of this, I limited the scope of my exposure assessment to exposures directly attributable to fluoridated water (0.7 mg/L). The purpose of my assessment was to enable a comparison of the doses people ingest from fluoridated water with the toxicity values (LOAELS and NOAELs) derived from the animal studies. I did not consider fluoride intake from dental products, pesticides, industrial pollution, occupational exposures, black tea, or other sources.

148. In my assessment, I considered fluoride exposures among both the general public as well as subsets of the population known to consume elevated amounts of water. For the source data, I relied primarily on the NRC's 2006 report which presented estimates of fluoride intake from water containing 0.7 mg/L fluoride. The NRC's estimates were based on an EPA analysis of community water intake data that were collected in a national survey by the US Department of Agriculture (USDA) in the 1990s.¹⁹² The USDA survey was "designed to obtain a statistically representative sample of the United States population," and EPA stated that data from this survey "may be used in risk assessment analyses where exposures that occur through ingestion of water are of concern."¹⁹³

149. Based on NRC's data, human exposure to fluoride from fluoridated water is estimated to range from an average of 0.011 mg/kg/day for adults to a "high" of 0.14 mg/kg/day for 95th percentile-exposed infants.

150. Following my initial report, a criticism was raised that I should have conducted a

¹⁹² The USDA survey is called the "Continuing Survey of Food Intakes by Individuals," or CSFII for short.

¹⁹³ EPA (2000a), p. 5-5.

systematic review of all water intake data published subsequent to the NRC's report. In response to this criticism, I reviewed an updated and comprehensive review of water intake data that EPA published in 2019. The review was published as an update to EPA's *Exposure Factors Handbook* ("*Handbook*"), which is a document "intended for use by exposure and risk assessors both within and outside the U.S. EPA as a reference tool and primary source of exposure factor information."¹⁹⁴

151. In its 2019 report, EPA presented the results of its "comprehensive review of the scientific literature [on water intake] through 2017" and provided EPA's determination as to "the most up-to-date and scientifically sound" data¹⁹⁵ to use for tap water consumption in the US.¹⁹⁶ The report thus provides the community water intake values¹⁹⁷ that EPA now recommends using for risk assessment for each age group in the population.¹⁹⁸

152. The water intake data that EPA identifies in its 2019 report are consistent with EPA's older water intake data that I relied upon in my initial assessment. For example, whereas I selected 0.011 mg/kg/day as an average adult exposure, the EPA's updated data produce mean intakes by adults of 0.011-0.013 mg/kg/day (i.e., the same as or slightly higher than my estimate).¹⁹⁹ Further, whereas I selected 0.14 mg/kg/day as the 95th percentile exposure among

¹⁹⁴ EPA (2011a), p. 1-3.

¹⁹⁵ EPA (2019b), p. 1-5.

¹⁹⁶ EPA selected its own analysis of water intake data from NHANES's 2005-2010 surveys as the "key study" to use for all age groups in the general population and for pregnant and lactating women. For formula-fed babies, EPA selected an analysis by Kahn of the USDA's CSFII survey, which is the same survey that the NRC relied upon for its estimates in 2006.

¹⁹⁷ EPA's report presents water intake in terms of milliliters of water consumed per kilogram of bodyweight per day (mL/kg/day). This permits a direct estimation of fluoride exposure from fluoridated water because the concentration of fluoride is known (0.7 micrograms per milliliter). By way of example, if a person drinks 100 milliliters of fluoridated water per kilogram of bodyweight, they will receive a dose of 70 micrograms of fluoride per kilogram, which is more commonly expressed as 0.07 milligrams per kilogram (i.e., 0.07 mg/kg/day).

¹⁹⁸ EPA (2019b), pp. 3-1, 3-4, 3-7, & 3-9.

¹⁹⁹ EPA (2019b), pp. 3-4.

bottle-fed infants, EPA's updated data produce 95th percentile values ranging from 0.13 mg/kg/day to 0.2 mg/kg/day (i.e., higher than my estimate).²⁰⁰

153. The similarity between the two EPA datasets can be seen in the following figure. The figure shows the fluoride exposure from water for *all* community water consumers for *all* age groups combined. The left side of the figure shows EPA's 2000 data (that NRC and I relied upon), while the right side of the figure shows EPA's 2019 data. To help put these exposures in context, the figure also shows the five reference doses from the animal neurotoxicity data (Table 5).

154. As can be seen in the figure, the two datasets show that a *substantial* percentage of the population that consume fluoridated tap water exceed each of the 5 RfDs for neurotoxicity, including the least protective RfD.

155. One limitation with EPA's water intake data (from both 2000 and 2019) is that they do not include consumption of community water that is added to commercial beverages, such as soda and juice.²⁰¹ This underestimates actual exposure to fluoridated water, since commercial

²⁰⁰ EPA (2019b), pp. 3-9.

²⁰¹ EPA (2000a), p. viii.

beverages have become a significant source of exposure to fluoridated water for many people.²⁰²

156. Another limitation with EPA's water intake data is that they are based on short-term surveys (i.e., surveys taken on two non-consecutive days), which creates a source of uncertainty when extrapolating to long-term exposures. This uncertainty is minimized, however, by the large numbers of people surveyed in the studies, and the use of non-consecutive days for the survey. While not perfect, EPA has recognized these data as the most scientifically sound data to use for risk assessment.

VIII. RISK CHARACTERIZATION

157. The risk characterization step of a risk assessment integrates the evidence of hazard, exposure, and dose-response in a clear and transparent manner, and provides a description of the risk. The *Guidelines* recognize multiple ways of describing risk, including (i) characterization of highly-exposed and/or susceptible individuals; (ii) estimation of the number of individuals exposed; (iii) comparing human exposures against the RfD; and (iv) "Margin of Exposure" analysis.²⁰³

A. Characterization of Highly Exposed and/or Highly Susceptible Populations

158. Susceptibility to a chemical may be "intrinsic" (biological, e.g., life stage) or "extrinsic" (acquired, e.g., lifestyle),²⁰⁴ although many individuals may have *both* intrinsic *and* extrinsic susceptibility.

159. EPA has recognized that life stage is an important source of intrinsic susceptibility to neurotoxicants, and has identified the prenatal, infant, and elderly stages of life as "critical periods for exposure."²⁰⁵ According to the EPA, "It is a well-established principle that there are

²⁰² E.g., Heilman et al. (1999); Kiritsy et al. (1996); Turner et al. (1998).

²⁰³ EPA (1998a), pp. 63-66.

²⁰⁴ EPA (2017).

²⁰⁵ EPA (1998a), p. 65.

critical developmental periods for the disruption of functional competence, which include both the prenatal and postnatal periods to the time of sexual maturation, and the effect of a toxicant is likely to vary depending on the time and degree of exposure.”²⁰⁶ In light of this, a “population subgroup is susceptible if exposure occurs during a period of sensitivity.”²⁰⁷

160. As described below, there are large, identifiable subsets of the population that are likely more susceptible to the neurotoxic effects of fluoride than the general population, including pregnant women and their fetuses, bottle-fed infants, the elderly, and individuals with renal impairment.

1. Pregnant Women and Their Fetuses

161. Multiple converging lines of evidence support the fetal period as a critical period of susceptibility to fluoride’s neurotoxic effects. First, it is well established that fluoride crosses the placenta and reaches the fetus.²⁰⁸ Second, due to the absence of an effective blood brain barrier,²⁰⁹ the fluoride that reaches the fetus also reaches the brain—a fact that has been confirmed by both animal and human studies.²¹⁰ Third, fluoride has the capacity to lower thyroid function, particularly among individuals with low iodine intakes, and EPA has recognized that alterations to thyroid function (e.g., reductions in thyroid hormone concentrations) during pregnancy can cause cognitive disorders and other neurological harm to the child.²¹¹ Fourth, most studies of prenatal fluoride exposures in animals have documented neuroanatomical, neurochemical, and/or cognitive problems. Fifth, all prospective cohort studies that included individual measurements of

prenatal fluoride exposure have found significant adverse associations with neurocognitive harm, including IQ loss and inattention.²¹²

162. The number of pregnant women exposed to fluoridated water each year is large. The CDC estimates that there are approximately 4 million children born in the U.S. each year, and therefore about 4 million pregnancies.²¹³ With approximately two-thirds of the U.S. population living in communities where fluoridation chemicals are added to water, about 2.5 million pregnancies can be expected to occur each year in fluoridated areas.

163. Of paramount concern are pregnant women who have an iodine deficiency. The CDC considers the average iodine status (median urinary iodine concentration) of women of childbearing age (12-19 years and 20-39 years) in the U.S. to be in the “adequate intake” range, but the 10th percentiles by ethnicity and for the total population are in the “insufficient intake” range, indicating that more than 10% of women of childbearing age in the U.S. are deficient in iodine.²¹⁴ Caldwell et al. report that 35% of pregnant women and 38% of nonpregnant women in the U.S. have urinary iodine concentrations below the level considered adequate.²¹⁵ In addition, the CDC notes that even higher intakes of iodine are required for pregnant and lactating women; thus an even greater percentage of American women are likely to be deficient in iodine with respect to the demands of pregnancy and lactation.²¹⁶ Pearce suggests that iodine deficiency in the U.S. may be becoming more prevalent, especially among pregnant women.²¹⁷

164. While the effects of fluoride exposure among pregnant women with iodine

²¹² Bashash et al. (2017; 2018); Green et al. (2019); Valdez-Jiménez et al. (2017).

²¹⁷ Pearce (2015).

deficiency have not yet been specifically studied, there is a clear basis for concern. The NRC reported that high fluoride intake appears to exacerbate the effects of low iodine intake on thyroid function in both animals and humans.²¹⁸ Consistent with this, Malin et al. found that an increase in urinary fluoride was associated with an increase in thyroid stimulating hormone (TSH)—an indicator of decreased thyroid function—among iodine-deficient adults in Canada.²¹⁹ A decrease in thyroid function during pregnancy, even in the absence of clinical symptoms in the mother, is associated with reduced IQ and other neurological effects in the offspring.²²⁰

2. Bottle-Fed Infants

165. A bottle-fed infant has a combination of *both* intrinsic *and* extrinsic susceptibility to fluoridated water.

166. *Intrinsic Susceptibility:* The blood brain barrier does not finish developing until 6 months of age,²²¹ and, as such, the fluoride ingested during early infancy will likely reach the brain more readily than during the later childhood and adult years. The brain is also undergoing “rapid development” during infancy, with the growth rate of the brain peaking at 4 months of age.²²² The EPA has thus described the neonatal stage of life as “a critical window of development.”²²³

167. *Extrinsic Susceptibility:* Infants have the highest intake of fluid per unit body weight of any age group among humans, given their mostly liquid diet at that age. This can be seen in the following figure, which uses EPA’s 2000 water intake data to compare the community water

²¹⁸ NRC (2006), pp. 227, 234, 262.

²¹⁹ Malin et al. (2018).

²²⁰ For example, see Haddow et al. (1999); Pop et al. (1999; 2003); Morreale de Escobar et al. (2000; 2004); Klein et al. (2001); Vermiglio et al. (2004); LaFranci et al. (2005); Kooistra et al. (2006); Roman (2007); Zoeller and Rovet (2004); Patel et al. (2011); Suárez-Rodríguez et al. (2012); Modesto et al. (2015); Moleti et al. (2016).

intake of adults (on the left) with the community water intake of bottle-fed infants (on the right).

Intakes based on EPA 2000 Water Intake Estimates in US, p. IV-3.

168. According to the CDC, 75% of infants born in 2015 were formula-fed at least partially during their first six months, including 17% of infants who were *exclusively* formula-fed.²²⁴ Data vary by ethnicity, with Hispanics, whites and Asians having breastfeeding rates similar to or greater than the national averages and African Americans having substantially lower rates. Breastfeeding rates tend to be highest for higher family income and maternal education levels.

169. Breastfeeding rates in the U.S. have increased substantially in recent years from a low point in the early 1970s.²²⁵ While increased breastfeeding rates are to be encouraged for a number of reasons, it is important to remember that for many infants in the U.S., breastfeeding is not an option; these include cases of infant adoption or fostering, as well as cases of death or illness of the mother.

²²⁴ CDC (2018; n.d.).

²²⁵ DHEW (1979), pp. 2-6, especially Tables A and B.

170. Most commercial infant formula, historically and currently, has been in powder form, for which the cost is approximately half that of ready-to-feed formula, per unit volume of formula as fed.²²⁶ Based on national data collected during 2005-2007, the CDC reported that approximately 83-93% of babies are fed formula prepared from powder from cans.²²⁷ For approximately 70-78% of infants in the same national survey, formula is reconstituted with tap water at least some of the time.²²⁸

171. Based on the available information, it can reasonably be assumed that the majority of formula-fed infants in the U.S. are fed powdered formula reconstituted with water, often or usually tap water. Especially for low-income homes (where breastfeeding is less likely), it is reasonable to assume that many or most infants are fed formula prepared from powder using tap water, which in much of the country is fluoridated. In addition, for approximately 20% of infants, tap water is boiled before it is used to prepare formula;²²⁹ if this tap water is fluoridated, the resulting fluoride concentration in the formula will be higher than if the water had not been boiled.²³⁰

172. Fomon et al. estimated that infants consuming powdered formula prepared with fluoridated water (1 mg/L) will ingest between 0.116 and 0.164 mg/kg/day.²³¹ If Fomon's estimate is adjusted to account for the lower concentration of fluoride now added to water (0.7 mg/L), the result is a daily intake of 0.08 to 0.115 mg/kg/day, which is 80 to 115 times higher than the amount that Fomon et al. estimated for breast-fed infants (0.001 mg/kg/day).²³² By Fomon's estimates,

²²⁶ O'Connor (2009).

²²⁷ CDC (2017), Table 3.16.

²²⁸ CDC (2017), Table 3.97.

²²⁹ CDC (2017), Table 3.98.

²³⁰ For example, see Juárez-López et al. (2011).

²³¹ Fomon et al. (2000), Table 2.

²³² Fomon et al. (2000), Table 2.

essentially all formula-fed infants will exceed the RfDs for neurotoxicity if their formula is prepared with fluoridated tap water.

173. Fomon's estimates agree well with recent data from Harriehausen et al., who surveyed 114 parents in Houston to determine brand and type of formula, total volume of formula consumed over 24 hours, and infant weight.²³³ Most of the parents in the study (corresponding to 92.1% of the infants) reported using powdered formula, which is consistent with the literature described above.²³⁴ Harriehausen et al. estimated that over 50% of infants fed formula made with fluoridated water will exceed 0.1 mg/kg/day during the first 4 months of life (Table 6).

Table 6. Estimated fluoride ingestion from infant formula, assuming fluoridated water at 0.7 mg/L.^a

Category	Age				
	2 months	4 months	6 months	9 months	12 months
Number of infants	32	23	27	21	11
Predicted fluoride intake					
Mean (mg/kg/day)	0.110	0.112	0.090	0.066	0.053
Variance	0.0033	0.0016	0.0018	0.0012	0.0009
Standard deviation ^b	0.057	0.040	0.042	0.035	0.03
Distribution of fluoride intake					
> 0.1 mg/kg/day (%)	59.4	56.5	33.3	14.3	9.1
< 0.1 mg/kg/day (%)	40.6	43.5	66.7	85.7	90.9

^a Data from Harriehausen et al. (2019), Table 3.

^b Calculated from the variance reported by Harriehausen et al. (2019), Table 3.

²³³ Harriehausen et al. (2019).

²³⁴ Harriehausen et al. (2019), Table 2.

174. The estimates from both Harriehausen and Fomon are consistent with EPA's most up-to-date and scientifically sound estimates for formula-fed infants.²³⁵ According to EPA's updated estimates, mean fluoride exposures during the first 6 months of life for infants receiving formula reconstituted with fluoridated water are **0.07 to 0.10 mg/kg/day** (age-dependent), with 95th percentile exposures of **0.13 to 0.2 mg/kg/day** for the first 3 months and **0.13 mg/kg/day** for the next three months.²³⁶ These intakes are very high, and far exceed even the least protective RfD, as shown in the following figure.

175. In its *Guidelines*, EPA considers the potential for postnatal toxicant exposures to interact with breastmilk composition.²³⁷ EPA was referring to animal studies, but the principle would apply to humans as well: Replacement of the mother's milk with a substitute that contains a toxic agent would be an extremely important source of postnatal exposure for infants and children

²³⁵ EPA (2019b), p. 3-9.

²³⁶ EPA (2019b), p. 3-9.

²³⁷ EPA (1998a), p. 46.

to that toxic agent. Few, if any, animal studies reproduce the effect of formula-feeding of human infants, in terms of a water-based formula containing fluoride being substituted for the mother's milk; thus this very important developmental period is routinely missed in most developmental studies on fluoride.

176. Consistent with the high fluoride intakes produced by formula feeding, studies have found that bottle-fed babies have higher rates of dental fluorosis (a disorder of enamel caused by excess fluoride intake) in their permanent teeth.²³⁸ Studies have also documented an increased prevalence and severity of dental fluorosis in the African American community, which is consistent with the high rate of formula feeding in this population.²³⁹

177. While fluoride exposure during infancy is known to produce abnormal physiological changes in the body (e.g., dental fluorosis), there has been a paucity of research on the neurodevelopmental effects of this exposure. In the developmental studies on fluoride neurotoxicity to date, the pups have been *breastfed*. Consequently, the existing animal data do not reflect the neurotoxic effects that may occur during the neonatal period.

178. Studies in humans have found lower IQ scores among formula-fed babies versus breastfed babies,²⁴⁰ but up until this year,²⁴¹ no study had investigated the role that fluoridated water may have in this association. Specific differences in brain activation and regional volumes of gray matter have been reported among formula-fed children, indicating developmental changes in children in comparison with breastfed children.²⁴² Such effects (and other adverse effects of

²³⁸ Hong et al. (2006a; 2006b); Forsman (1977); Walton and Messer (1981); Fomon and Ekstrand (1999); Fomon et al. (2000).

²³⁹ EPA (2010), pp. 33-34; Exhibit 34 to Casey Hannan Deposition; CDC (2005), Table 23.

²⁴⁰ For example, see Fomon (2001); Wolf 2003; Belfort et al. (2013); Horta et al. (2015; 2018); Victora et al. (2015; 2016); Kanazawa (2015); Boutwell et al. (2018). Many studies have controlled for possible confounders such as maternal IQ, maternal education, and family income.

²⁴¹ Till et al. (2020).

²⁴² Ou et al. (2016).

formula-feeding compared with breastfeeding, especially compared with exclusive breastfeeding for at least the first several months) could, in principle, be due to loss of the enhanced mother-child bonding associated with breast-feeding,²⁴³ to deficiency of an essential nutrient (e.g., long-chain saturated fatty acids) in the formula,²⁴⁴ to the presence of a toxic contaminant in the water used to prepare the infant formula,²⁴⁵ or to some combination of these factors.

179. Given the *a priori* basis for concern that fluoridated water may adversely affect the neurological system of bottle-fed infants, the recent findings from Till et al. must be taken very seriously.²⁴⁶ Using a prospective cohort study design, Till et al. found that fluoridated water consumption during infancy is associated with a large and significant reduction in non-verbal IQ at age 4 (i.e., a loss of 9.3 non-verbal IQ points for each 0.5 mg/L increase in exposure). Although the study did not find a statistically significant association with Full-Scale IQ after excluding several outliers, this could be a result of imprecision in the exposure estimates, or might reflect differential impacts of pre- and post-natal exposure.

180. As noted earlier, CDC data indicate that 17% of babies are *exclusively* fed formula for their first six months of life (i.e., never breast-fed).²⁴⁷ Assuming 2.5 million live births per year in fluoridated areas, approximately 1.9 million infants living in fluoridated areas will be formula-fed for at least part of the time during their first six months, including 425,000 infants who are *exclusively* formula-fed.²⁴⁸ Approximately 70-78% of these infants will have their formula made

²⁴⁸ CDC (2018; n.d.).

with fluoridated tap water (some of which will be boiled and have higher concentrations), at least part of the time.²⁴⁹

3. Elderly

181. The elderly have also been identified by the EPA as an at-risk group for neurotoxicity.²⁵⁰ According to the EPA, the elderly are “at particular risk because of the limited ability of the nervous system to regenerate or compensate to neurotoxic insult.”²⁵¹

182. The NRC has described the possible relationship of fluoride exposure, especially exposure to aluminum fluoride complexes, to the development of Alzheimer’s disease.²⁵² The NRC based its concern, in part, on studies reporting pathological lesions in the brain of fluoride-treated rodents that parallel the changes in humans with dementia.²⁵³ A recent study by Cao et al. found that exposure to fluoride for 3 months among mice genetically prone to degenerative brain changes, produced more severe, and earlier development of, neuropathological lesions than in controls, including lesions associated with Alzheimer’s.²⁵⁴ Goschorska et al. have recently postulated that fluoride plays a likely role in the initiation and progression of Alzheimer’s disease, based largely on the neuroanatomical and neurochemical changes seen in the brains of fluoride-treated animals.²⁵⁵

183. While epidemiological data on fluoride and cognition in the elderly remain relatively sparse, Li et al. reported a very high rate of cognitive impairment (81.1%) in an endemic fluorosis area.²⁵⁶ Li did not find a linear relationship between urinary fluoride and the severity of

²⁴⁹ CDC (2017), Table 3.97; Juárez-López et al. (2011).

²⁵⁰ EPA (1998a), p. 65; see also NRC (2006), p. 351.

²⁵¹ EPA (1998a), p. 65.

²⁵² NRC (2006), pp. 210-212.

²⁵³ NRC (2006), pp. 222.

²⁵⁴ Cao et al. (2019).

²⁵⁵ Goschorska et al. (2018).

²⁵⁶ Li et al. (2016), p. 59.

cognitive impairment within the endemic fluorosis area; however urinary fluoride levels among those with any form of cognitive impairment were significantly higher than those with normal cognition.²⁵⁷ Russ et al. described a longitudinal study involving nearly all people born in Scotland in 1921, who were passively followed for diagnoses of dementia after 2004.²⁵⁸ Residential locations after age 60 (or at death or at time of diagnosis of dementia) were used to estimate exposure to aluminum and fluoride (separately) in drinking water. The authors found that even relatively low levels of aluminum and fluoride were associated with an increased prevalence of dementia and suggested further research.²⁵⁹

184. While more research is needed to clarify fluoride's effects in the elderly population, there are a multitude of factors which support an increased vulnerability to fluoride's neurological effects among the elderly. Studies have found that water fluoridation significantly increases the level of fluoride in bone, and these levels increase with age.²⁶⁰ In the post-menopausal and elderly years, the fluoride that is taken into bone can be released back into the blood stream as bones begin to break down, leading to increased levels of fluoride in the blood.²⁶¹ Compounding this, renal function declines with age, and because of this the elderly kidney can be expected to be less efficient in clearing fluoride from the bloodstream. The net result is that more fluoride will be circulating in the bloodstream, and due to age-related increases in the permeability of the blood-brain barrier, will reach the brain more readily.²⁶²

185. Although the impact of fluoride on the elderly brain has not received as much

²⁵⁷ Li et al. (2016), Figure 2, Table 3.

²⁵⁸ Russ et al. (2019).

²⁵⁹ Russ et al. (2019).

²⁶⁰ Alhava et al. (1980); Arnala et al. (1985); Eble et al. (1992); Chachra et al. (2010).

²⁶¹ Itai et al. (2010).

²⁶² Increased permeability of the blood-brain barrier is associated with ordinary aging, as well as with diseases such as Alzheimer's and Parkinson's, both of which are common among elderly people. For example, see Mooradian (1994); Zeevi et al. (2010); Rosenberg (2014); and Pan and Nicolazzo (2018).

scholarly attention as the impact on the developing brain, this population is likely at higher risk of toxicity than healthy adults, particularly among those with elevated accumulation of fluoride in the bone following long-term residence in a fluoridated area.

Renal Impairment

186. It is well recognized that people with renal impairment (kidney disease) are less able to excrete fluoride, resulting in higher concentrations of fluoride in the body and greater susceptibility to adverse health effects from fluoride exposure.²⁶³ The World Health Organization states that it “is known that persons suffering from certain forms of renal impairment have a lower margin of safety for the effects of fluoride than the average person.”²⁶⁴ In addition, a number of papers report an association between renal impairment and reduced IQ or other cognitive impairment,²⁶⁵ which is consistent with higher fluoride retention (and often higher water intake and consequent higher fluoride intake). The role of fluoride in these IQ deficits has not yet been the subject of epidemiological study.

4. Other Predisposing Factors

187. There are a number of other factors that are known, or reasonably anticipated, to increase susceptibility to the chronic toxic effects of fluoride exposure, including neurotoxicity. These factors include:

188. *Diseases that Increase Water Intake*: The NRC identified population subgroups whose water intake “is likely to be substantially above the national average for the corresponding sex and age group” as susceptible subpopulations with respect to fluoride exposure.²⁶⁶ Health

²⁶³ For example, see Marumo and Iwanami (2001); NRC (2006), pp. 30, 292, 351; Ibarra-Santana (2007); Schiff (2008).

²⁶⁴ WHO (2004), p. 6.

²⁶⁵ For example, see Madero et al. (2008); Mendley et al. (2015); Chen et al. (2018b).

²⁶⁶ NRC (2006), p. 30.

conditions that affect water intake include “diabetes mellitus, especially if untreated or poorly controlled; disorders of water and sodium metabolism, such as diabetes insipidus; [and] renal problems resulting in reduced clearance of fluoride.”²⁶⁷ According to the NRC, adults with diabetes mellitus can ingest 0.05 mg/kg/day from fluoridated water alone, while children with diabetes mellitus can have fluoride intakes as high as 0.07 mg/kg/day.²⁶⁸ For children and adults with nephrogenic diabetes insipidus, NRC estimated waterborne fluoride intakes of 0.11 mg/kg/day.^{269,270} Each of these intakes exceeds the least protective RfD.

189. *Nutrient Deficiencies:* Nutritional deficiencies can contribute to increased susceptibility to fluoride toxicity.²⁷¹ Calcium deficiency and iodine deficiency are expected to be particularly important in terms of vulnerability to neurotoxic effects of fluoride, but deficiencies of magnesium, vitamin C, protein, and other nutrients have also been associated with increased susceptibility to the effects of fluoride exposure.

190. *Genetic Susceptibilities:* A number of studies have shown associations between specific genetic arrangements and a greater susceptibility to the chronic effects of fluoride exposure,²⁷² including dental fluorosis and alterations to reproductive hormones.²⁷³ While a complete picture of the relationship between genes, gene regulation, and adverse effects of fluoride exposure remains to be developed, it is already quite clear that some people or groups of people

²⁶⁷ NRC (2006), p. 30.

²⁶⁸ NRC (2006), p. 35, Table 2-4.

²⁶⁹ NRC (2006), p. 35, Table 2-4.

²⁷⁰ Consistent with this, case reports have documented moderate to severe dental fluorosis among children with diabetes insipidus who drank water with 0.5 to 1 mg/L NRC (2006), p. 33.

²⁷¹ See for example, NRC (2006), p. 265; Pandit et al. (1940); Marier (1977).

²⁷² Reviewed by Pramanik and Saha (2017). See also Lavryashina et al. (2003); Tu et al. (2011); Liu et al. (2006); Huang et al. (2008); Ba et al. (2011); Zhao et al. (2015); Zhou et al. (2016); Zhang et al. (2013b); Pei et al. (2017); Jiang et al. (2015); Zhang et al. (2015b); Cui et al. (2018); K  chler et al. (2018); Bhagavatula Naga (2009).

²⁷³ Zhao et al. (2015); Zhou et al. (2016); Ma et al. (2017); An et al. (2019).

are inherently more vulnerable than others to adverse effects of fluoride exposure and require a greater level of protection from fluoride exposures.²⁷⁴ The implications to neurotoxicity have not yet been extensively studied, but two recent studies from China, including one with extensive control for covariates, suggest that certain genotypes may significantly magnify fluoride's impact on IQ in some individuals.²⁷⁵ A third, smaller study reported a contrary result.²⁷⁶ More research is needed to clarify this issue, but in light of the broader literature on genetic susceptibility to chronic fluoride toxicity, it is reasonable to suspect that genetics plays a role in rendering some individuals more vulnerable to fluoride's neurological effects.

B. Margin of Exposure (MOE)

1. Introduction to the MOE Approach and Its Similarity to the RfD Approach

191. Under the *Guidelines*, neurotoxic risk can be described either through a comparison of the human exposures to the RfD, or by calculating the “Margin of Exposure” (MOE).²⁷⁷ Although the two approaches use slightly different frameworks, they produce the same results. If comparison of human exposure with the RfD shows a risk, a risk will be shown by MOE as well, and vice versa.

192. RfD and MOE analyses produce the same results because they use the same Point of Departure (i.e., NOAEL, LOAEL, or BMDL) for the toxicity value, the same data for human exposure, and the same composite uncertainty factor to assess whether human exposure poses a risk. Where the two methods differ is in how they put these three pieces together and the terminology they use, as will now be discussed.

193. In an RfD analysis, human exposure is compared against the Reference Dose. As

²⁷⁴ Wu et al. (2015); Yang et al. (2016); Pei et al. (2017); Li et al. (2017); Yang et al. (2018b).

²⁷⁵ Cui et al. (2018); Zhang et al. (2015b).

²⁷⁶ Pang et al. (2018).

²⁷⁷ EPA (1998a), pp. 65-66; Federal Register (1998), pp. 26949-26950.

discussed earlier, the Reference Dose is the Point of Departure (i.e., NOAEL, LOAEL, or BMDL) divided by the composite uncertainty factor. In an MOE analysis, by contrast, human exposure is *compared directly against the Point of Departure*. If the ratio (i.e., Actual MOE) between the Point of Departure and human exposure is less than the composite uncertainty factor (i.e., Acceptable MOE), an unacceptable risk is presumed to exist.^{278,279} In short, the composite uncertainty factor is the standard for judging whether human exposure is unacceptably close to the toxicity value under both frameworks.

2. MOE Analysis

194. As part of the risk assessment, I conducted an MOE analysis to characterize risk because this is EPA's preferred method to characterize non-cancer risk under TSCA, as evident by its risk evaluations under both Section 5 (new chemicals)²⁸⁰ and Section 6 (existing chemicals).²⁸¹

195. *Points of Departure*: The same five Points of Departure (converted into Human Equivalent Doses) that were used for the derivation of the Reference Doses, as discussed above (see Table 5), were used for the MOE analysis.

196. *Acceptable MOEs (Benchmark MOEs)*: The same composite uncertainty factors that were used for the RfD derivation were selected as the Acceptable MOEs: 30 for the NOAEL-based PODs, and 300 for the LOAEL-based PODs. In EPA's draft risk evaluations under Section 6 of TSCA, EPA has used composite uncertainty factors of 30 for NOAEL-based PODs, and has

²⁷⁸ EPA (2016), p. 61; EPA (2012), p. 13-8.

²⁷⁹ EPA sometimes refers to the risk as a "risk of concern." EPA (2007), p. 13; EPA (2000c), p. C-12.

²⁸⁰ See for example EPA (2018b; 2018c; 2018d; 2018e; 2018f; 2018g; 2019a).

²⁸¹ In its draft risk evaluations under Section 6 thus far, EPA has used MOE to characterize non-cancer risk. (EPA 2019c; 2019d; 2020). In its Final Rule for Risk Evaluation under Section 6, however, EPA described the MOE method as "just one of several approaches to risk characterization" that may be used under TSCA (Federal Register 2017, p. 33735).

characterized this as a relatively small uncertainty factor that “indicates greater certainty in the data (because fewer of the default UFs relevant to a given POD . . . were applied).”²⁸² EPA has contrasted this with a composite uncertainty factor of 1,000, which “would indicate more uncertainty in risk estimation and extrapolation.”²⁸³

197. *Human Exposure:* At the time I conducted this analysis, EPA had not yet released any of its Section 6 draft risk evaluations. I relied, therefore, on EPA’s risk evaluations under Section 5 for guidance on the human exposure assessment. In the Section 5 risk evaluations, EPA considers the highest-exposed group in the population. When dealing with chemicals that may be present in drinking water, therefore, EPA’s MOE analyses separately consider the exposures of *infants*.²⁸⁴

198. Based on the guidance from the Section 5 risk evaluations, I relied on the NRC’s 2006 data to calculate a range of exposures representing the general adult population along with highly exposed population subgroups, including bottle-fed infants and individuals with high water intakes (for example, due to medical conditions or to physical exertion).²⁸⁵

199. In EPA’s draft risk evaluations under Section 6, EPA has used the 95th percentile exposure to represent highly exposed individuals.²⁸⁶ This is the same percentile exposure I used

²⁸² EPA (2019d), p. 301.

²⁸³ EPA (2019d), p. 301.

²⁸⁴ See for example EPA (2018b; 2018c; 2018d; 2018e; 2018f; 2018g; 2019a).

²⁸⁵ For the general adult population, I combined NRC’s estimates for adult consumers of municipal water, ages 20-24 and 25-54 years (0.011 mg/kg/day). As an example of elderly adults (ages 65+), I included the 90th percentile of adult consumers of municipal water (0.022 mg/kg/day). To account for individuals with high water intakes, I used the NRC’s waterborne fluoride intake estimates (at 0.7 mg/L) for adult athletes and physical laborers (0.05 mg/kg/day), children with diabetes mellitus (0.07 mg/kg/day), and individuals with nephrogenic diabetes insipidus (0.1 mg/kg/day). For bottle-fed infants, I estimated a typical (0.1 mg/kg/day) and high (0.14 mg/kg/day) exposure based on the data from Fomon et al. (2000), Harriehausen et al. (2019), and NRC (2006). None of these exposure estimates, even those labeled “high,” is an upper bound or maximum exposure.

²⁸⁶ E.g., EPA (2019d), pp. 266, 300; EPA (2020), p. 108.

for high exposures among bottle-fed infants, and a higher percentile exposure than I used for the elderly (90th percentile).

200. Table 7 and the two figures below show the results of the MOE analyses. The first figure shows the results using the three LOAEL-Based PODs, while the second figure shows the results using the NOAEL-based PODs. As can be seen, the Actual MOEs are below the Acceptable MOEs for each group using every POD (including the least protective), with the exception of *average* adults and 90th percentile elderly when using the NOAEL-based PODs. If EPA's recommended 95th percentile exposure data (0.031 mg/kg/day) is used as the exposure for adults, risks are present even when using the least protective PODs.

201. The margins between the neurotoxicity levels in animals and the exposure levels in humans are far smaller than what EPA considers "acceptable." In fact, the Actual MOEs are so small that unacceptable risks would still be indicated for infants for each POD if the doses from animal studies had no adjustment to convert to the Human Equivalent Doses (HEDs) (i.e., no allometric scaling). Under EPA's framework for characterizing risk, therefore, it is apparent that fluoridation chemicals in drinking water present an unacceptable risk of neurotoxicity.²⁸⁷

²⁸⁷ EPA (2016), p. 61.

Table 7. Calculated Margins of Exposure (MOEs)^a for selected subgroups of the human population for the NOAELs and LOAELs for fluoride in Table 5.

Observation ^b	Intake rate ^c	Human Equivalent Dose (HED) ^d	Estimated human exposures ^e					
LOAEL or NOAEL	LOAEL or NOAEL	LOAEL or NOAEL	Adults (average)	Elderly adults (90th percentile)	Athletes and laborers (high)	DM patients (high)	Bottle-fed infants (typical) NDI patients (high)	Bottle-fed infants (high)
mg/L	mg/kg/day	mg/kg/day	0.011 mg/kg/day	0.022 mg/kg/day	0.05 mg/kg/day	0.07 mg/kg/day	0.1 mg/kg/day	0.14 mg/kg/day
5 mg/L, LOAEL (rats)	0.83	0.20	18	9.1	4.0	2.9	2.0	1.4
23 mg/L, LOAEL (rats)	3.8	0.91	83	41	18	13	9.1	6.5
45 mg/L, LOAEL (rats)	7.5	1.8	163	82	36	26	18	13
11 mg/L, NOAEL (mice)	2.9	0.41	37	19	8.2	5.9	4.1	2.9
20 mg/L, NOAEL (rats)	3.3	0.79	72	36	16	11	7.9	5.6

^a A Margin of Exposure (MOE) is equal to the LOAEL or NOAEL (mg/kg/day) divided by an estimated human exposure (mg/kg/day). Usually, the benchmark MOE = 1000 for assessments based on a LOAEL and 100 for assessments based on an NOAEL. Since allometric scaling between animals and humans has been used to obtain the Human Equivalent Dose, the benchmark MOE is 300 for LOAELs and 30 for NOAELs. An MOE less than the benchmark MOE indicates an “unacceptable risk.”

^b These LOAEL and NOAEL values (mg/L) for fluoride are summarized in Table 2.

^c The intake rates (mg/kg/day) in this column correspond to the LOAELs and NOAELs in the first column (mg/L), converted to intake rates (mg/kg/day) as summarized in Table 5. For rats, the intake rate equals the LOAEL or NOAEL divided by 6. For mice, the intake rate equals the NOAEL divided by 3.8.

^d The Human Equivalent Dose (HED) is calculated from the intake rate for rats or mice as summarized in Table 5. The HED = the intake rate for rats × 0.24 or the intake rate for mice × 0.14.

^e The estimated human exposures are for fluoride exposures from drinking water alone, assuming a fluoride concentration of 0.7 mg/L in the drinking water. Sources are as follows: Adults (average), NRC (2006), p. 430, Table B-11, average consumers ages 20-54; Elderly adults (90th percentile), NRC (2006), p. 431, Table B-12, 90th percentile consumers ages 65+; Athletes and laborers (high), NRC (2006), p. 35, Table 2-4, high consumers (but not upper bound); DM patients (high), NRC (2006), p. 35, Table 2-4, patients with diabetes mellitus, high consumers (but not upper bound); Bottle-fed infants (typical), based on Fomon et al. (2000) and Harriehausen et al. (2019); NDI patients (high), NRC (2006), p. 35, Table 2-4, patients with nephrogenic diabetes insipidus, high consumers (but not upper bound); and Bottle-fed infants (high), NRC (2006), p. 432, Table B-13, infants < 0.5 years old, 95th percentile consumers (but not upper bound).

C. Assumptions and Key Sources of Uncertainty

202. Uncertainties are inherent to the field of risk assessment; they are to be expected. As discussed throughout my expert report, there are uncertainties involved in a risk assessment of fluoride neurotoxicity,²⁸⁸ including:

203. *Uncertainties in the Animal Data:* The Points of Departure for both the RfDs and MOEs are derived from developmental animal studies that, while published in the peer-reviewed biomedical literature, have methodological limitations, including lack of control for litter effects, lack of blinding, lack of exposure during the full window of vulnerability (in utero *and* infancy), lack of long-term chronic exposures, and failure to rule out a contributing role of motor and sensory effects in the observed learning/memory deficits. As discussed earlier, the net effect of these limitations is uncertain. On one hand, lack of blinding can inflate the effect size, while on the other hand, lack of exposure during the full window of vulnerability and lack of chronic exposures can deflate it. Similarly, while lack of control for litter effects can create false positives, it can also create false negatives as well.²⁸⁹ Further, to the extent that fluoride is causing the learning/memory deficits indirectly through a motor/sensory mechanism,²⁹⁰ this would still be a neurotoxic effect and is thus not a basis to forego risk assessment, particularly since body weight changes do not appear to be a mediating mechanism in the studies from which the Points of Departure have been derived.

²⁸⁸ For purposes of brevity, my initial expert report did not reiterate each of these uncertainties in the risk characterization section, although I considered them as part of my assessment.

²⁸⁹ Zorrilla (1997), p. 144; Lazic and Essioux (2013), p. 3.

²⁹⁰ NTP (2016), p. vii.

204. While there are some uncertainties in the animal data (which is not unusual²⁹¹), there is reasonable confidence that the observed effects are both real and relevant. First, the animal studies have been overwhelmingly consistent—across numerous laboratories and study designs—in finding adverse effects on the brain, both structural and functional, which supports the conclusion that the effects are not an artifact of a methodological limitation. Second, the effect of fluoride on cognition has been detected in studies that have specifically controlled for litter effects and body weight changes, thus suggesting that fluoride’s effect on the brain is independent of these concerns.²⁹² Third, there are extensive human epidemiological data reporting associations between fluoride and reduced IQ, and the existence of these data adds plausibility to the animal data, and vice versa. Fourth, the finding of unacceptable risk through an MOE analysis of the animal toxicity values is consistent with Dr. Grandjean’s BMD analysis of the human data, which shows that the level of exposure associated with reduced IQ in humans is well below the levels of exposure produced by fluoridation. The confluence of the animal and human data thus adds strong overall confidence to the assessment.

205. *Uncertainties in the Extrapolation to Humans:* As discussed above, the extrapolation of animal data to humans involves some inherent uncertainty. There does not yet exist a physiologically based toxicokinetic model (PBTK) for fluoride, which would be the optimal method for adjusting for toxicokinetics.²⁹³ This uncertainty has been accounted for by EPA’s use of allometric scaling method which accounts for the expected difference in

²⁹¹ As discussed earlier, the principal animal studies that EPA has relied upon for its neurotoxicity risk assessments have also had methodological limitations, including failure to control for litter effects. There was also significant uncertainty in the animal data that EPA used for its unreasonable risk determinations for its draft NMP evaluation (e.g., there were only 6 studies available for the endpoint of concern, and three found no effect).

²⁹² Bartos (2018; 2019).

²⁹³ EPA (2011b), p. 19.

toxicokinetics), and use of an uncertainty factor of 3 (to address the expected difference in toxicodynamics). The use of default allometric scaling for fluoride is consistent with chemical-specific research on fluoride showing that rats and mice require approximately 5 to 10 times more fluoride, respectively, to obtain the same concentration of fluoride in the blood.²⁹⁴ The allometric scaling thus has a chemical-specific justification for fluoride, which provides confidence to the assessment. But, importantly, even if *no* allometric scaling is done to assess the risk of infant exposures, the MOEs still indicate unacceptable risks for *all* PODs.

206. The use of non-protective (i.e., non-conservative) assumptions provides additional confidence to the assessment. These non-protective assumptions include: (1) the use of 45 mg/L as a LOAEL, despite the fact that studies have found adverse effects well below this concentration; (2) the use of 20 mg/L as a NOAEL in McPherson (2018), despite the fact that the study found a neurotoxic effect at this concentration (i.e., increased pain sensitivity); and (3) conversion of water fluoride concentrations (mg/L) into doses (mg/kg/day) using the lowest end of the reported ratio, which results in Points of Departure that are likely higher than the actual dosages the animals received.

207. *Uncertainties in the Exposure Assessment:* As discussed above, I obtained most of my initial exposure estimates from the NRC's 2006 report, which in turn were based on EPA's own water intake data from 2000,²⁹⁵ and have also reviewed EPA's 2019 report in which the Agency identified the "most up-to-date and scientifically sound" water intake data to use for risk assessment. Both of EPA's water intake reports (from 2000 and 2019) are based on short-term (2-day) surveys, which introduces some uncertainty when extrapolating to long-term exposures.

²⁹⁴ NRC (2006), pp. 98, 442; Zhang et al. (2014).

²⁹⁵ NRC (2006), Appendix B; EPA (2000a).

Long-term surveys, however, do not exist, and the uncertainty of using 2-day surveys is minimized by the large, nationally-representative scale of the survey data. EPA has stated that it has medium-to-high confidence in the reliability of these data, and that the data are well suited for risk assessment of water-based exposures.²⁹⁶

208. *Uncertainties in the Human Data:* One of the major strengths of the database on fluoride neurotoxicity is that there is a large body of human data, including five prospective cohort studies that have individual measurements of exposure during the fetal and neonatal period. The large extent of human data for fluoride far surpasses what EPA has used for its draft risk assessments of other chemicals under Section 6,²⁹⁷ where the Agency has often had to rely *solely* on animal data.

209. The emergence of prospective cohort data on early life exposures to “optimal” levels of fluoride (from salt and water fluoridation programs)²⁹⁸ addresses the two primary criticisms that have been made with respect to the cross-sectional studies of populations with elevated levels of fluoride in water: i.e., (1) that cross-sectional studies are limited in establishing causation because the exposures are measured after the effect (i.e., IQ loss) has occurred; and (2) the cross-sectional studies involve exposures that are generally higher than what people receive through artificially fluoridated water. The fact that the prospective cohort studies have found cognitive deficits at “optimal” levels of exposure that are consistent with the effects observed in the cross-sectional studies adds *substantial* confidence to the risk characterization.

210. While the human data are very robust, data gaps do remain, particularly with

²⁹⁶ EPA (2000a), p. 5-5; EPA (2019b), pp. 3-6 & 3-10.

²⁹⁷ As discussed earlier, the data available for fluoride are also substantially more robust than the data EPA has considered in making hazard determinations for other neurotoxicants.

²⁹⁸ I understand that Dr. Hu and Dr. Lanphear will be addressing the criticisms with respect to imprecise exposure estimates, and thus I do not address that issue here.

respect to how the causative doses may vary across the population based on life-stage (e.g., the elderly), and other intrinsic sources of susceptibility, such as renal impairment, nutritional deficiencies, and genetic predisposition. These data gaps make it difficult to quantify the extent to which susceptibility varies across the population; the available data on chronic fluoride toxicity, however, provide a high level of confidence that human susceptibility to fluoride varies by a considerable margin, particularly in a population as large and diverse as the United States. Of particular concern are individuals with co-existing susceptibilities, such as pregnant women with iodine deficiencies, neonates that are bottle-fed with fluoridated water, and elderly individuals with diabetes.

211. To account for the *known* (but not yet quantified) variability in human susceptibility, I utilized EPA's default uncertainty factor of 10. This is consistent with EPA's standard practice, including EPA's Section 6 risk evaluations under TSCA. While I derived the Points of Departure from studies on susceptible (i.e., prenatally exposed) animals, the studies did not account for the full range of expected susceptibility in the human population. The studies did not, for example, attempt to replicate the formula-feeding practices of human infants, as all rodents were breast-fed during the critical neonatal period. Nor did the studies attempt to examine the effect of a co-existing iodine deficiency in the mother, or any other factor (e.g., renal impairment, calcium deficiency, etc) that would be expected to exacerbate the effects of prenatal fluoride exposure. Since hundreds of millions of Americans are now exposed to fluoridation chemicals on a regular basis, the spectrum of susceptibility will likely exceed the susceptibility examined in the available animal studies. An uncertainty factor of 10 is thus appropriate and necessary.

IX. RISK DETERMINATION

212. Under TSCA, a risk evaluation has a fifth and final step that is not included within the *Guidelines*: the Risk Determination. In the Risk Determination, EPA assesses whether the risks identified by the Margin of Exposure (MOE) analysis are “unreasonable.” In making this determination, EPA considers “relevant risk-related factors,” including (i) the effects of the chemical substance under the conditions of use; (ii) number of people exposed; (iii) whether susceptible subpopulations are exposed; (iv) the severity of the hazard; and (v) uncertainties in the data.

213. In practice, EPA’s Risk Determination analyses do not address each of the “relevant risk factors” identified above. Severity of the hazard, for example, is rarely discussed. Assessments of uncertainties in EPA’s Risk Determinations has also been rather cursory. In the NMP risk evaluation, for instance, the discussion of uncertainties in the analysis was largely limited to the assumptions involved in estimating worker exposure to chemicals in the absence of actual monitoring data.²⁹⁹ Although EPA’s risk estimates were based on an endpoint for which there were only 6 animal studies (with only 3 showing an effect), EPA did not re-address the underlying uncertainties in these data. The Risk Determination should thus not be mistaken as an exhaustive re-examination of all issues previously addressed; instead they tend to be brief and written in summary form.

214. At the time I conducted my initial assessment in this case, EPA had not yet released any risk evaluations under Section 6. For guidance, therefore, I relied on the risk characterization

²⁹⁹ EPA (2019d), pp. 301-335.

considerations identified in the *Guidelines*,³⁰⁰ as well as risk evaluations that EPA had recently completed on “new chemicals” under Section 5.

215. The factors that EPA considers under Section 5 substantially overlap with the factors that EPA considers under Section 6. Specifically, EPA considers the following three factors: (i) the hazardous nature of the chemical (as determined by toxicity values in animal studies);³⁰¹ (ii) the extent of human exposure to the chemical, and (iii) the Margin of Exposure (MOE). As I described in my report, fluoride meets each of these three criteria for unreasonable risk.

216. Importantly, whether one considers the factors under Section 5 or Section 6, the risk of neurotoxicity posed by fluoridation chemicals constitutes a clear and unreasonable risk, as will now be discussed.

A. Effects of Fluoridation Chemicals Under the Condition of Use

217. In most of the risk evaluations that EPA has conducted thus far under Section 6, the Agency did not have actual human data on health effects associated with the condition of use. EPA had to rely, therefore, on animal data alone. This is not the case with fluoridation. Critically, there are four prospective cohort studies that have examined the impact of optimal fluoride exposures, including two that examined the specific condition of use (water fluoridation) at issue.³⁰² Under the *Guidelines*, prospective cohort data permit “direct estimates of risks attributed to a particular

³⁰⁰ EPA (1998a), pp. 63-66.

³⁰¹ Under Section 5, a chemical is “considered to have high human health hazard if there is evidence of adverse effects in humans or conclusive evidence of severe effects in animal studies with a **NOAEL** of less than or equal to 10 mg/kg/day.” EPA (2018b; 2018c; 2018d; 2018e; 2018f; 2018g; 2019a). This criterion is readily satisfied with fluoride, as the **LOAELs** for cognitive deficits and brain abnormalities are below 10 mg/kg/day. Fluoride is thus a “high human health hazard” under Section 5.

³⁰² Bashash et al (2017, 2018); Green et al. (2019); Till et al. (2020).

exposure.”³⁰³ The effects of fluoridation chemicals under the condition of use are thus well characterized, particularly in comparison to chemicals (e.g., NMP, 1-BP) for which EPA has made unreasonable risk findings under TSCA.

B. Number of People Exposed to Fluoridation Chemicals

218. EPA has recognized that “the significance of the risk is dependent upon both the hazard (or toxicity) of the chemical substance and *the extent of exposure* to the substance.”³⁰⁴ Although EPA made this statement in the context of Section 5, EPA considers the extent of exposure to be a relevant factor under Section 6 as well. In the Section 6 risk determinations, the number of people (usually workers) who are exposed to the chemical are identified under each condition of use.³⁰⁵

219. This factor weighs in favor of an unreasonable risk finding for fluoridation chemicals. The extent of human exposure to fluoridation chemicals is nothing short of massive, much like lead exposure was during the era of leaded gasoline. Today, approximately 200 million Americans, or nearly 2/3 of the population, have municipal water to which fluoridation chemicals are added. Moreover, most of the remaining population living in “non-fluoridated” areas will routinely consume fluoridation chemicals in processed beverages and foods, as many beverages and foods are produced in fluoridated areas.³⁰⁶ To put these numbers in perspective, EPA has found unreasonable risks for conditions of use involving as few as 1,046³⁰⁷ and 1,900 occupationally-

³⁰³ EPA (1998a), p. 17.

³⁰⁴ EPA (2018b; 2018c; 2018d; 2018e; 2018f; 2018g; 2019a).

³⁰⁷ EPA (2019c), p. 264.

exposed workers.³⁰⁸ With such widespread exposure to fluoridation chemicals among the general population, even small risks can amount to widespread harm.

C. Exposure of Susceptible Subpopulations to Fluoridation Chemicals

220. One of the consequences from widely dispersing a toxicant through the environment (versus the use of industrial chemicals *within* manufacturing facilities) is that susceptible members of the general public may be exposed. This is the case with fluoridation chemicals. Each year, there are approximately **2.5 million pregnancies** in fluoridated areas; *in utero* exposures are thus widespread. Many of those exposed *in utero* will also be exposed during the sensitive neonatal period, with upwards of **1.9 million infants** living in fluoridated areas being fed formula at least part of the time, including **400,000 infants** who are *exclusively* formula-fed for their first six months. While these numbers do not account for those who use bottled water, the numbers will be substantial regardless.

D. The Severity of the Hazard (Cognitive Deficits/IQ Loss)

221. The principal hazard at issue from exposure to fluoridation chemicals is IQ loss. The prospective studies have found an approximate 5 to 6 point drop in IQ as maternal urinary fluoride levels increase from 0 to 1 mg/L.³⁰⁹ To put this in perspective, EPA has recognized that a loss of a single IQ point is associated with a loss in lifetime earnings,³¹⁰ and EPA's Clean Air Science Advisory Council has stated that "a population loss of 1-2 IQ points is highly significant from a public health perspective" and should be prevented in 99.5% of the population.³¹¹

³⁰⁸ EPA (2019d), pp. 307, 311.

³⁰⁹ Bashash et al. (2017); Green et al. (2019).

³¹⁰ EPA (2008e), p. 5-28.

³¹¹ Federal Register (2008), p. 67000.

Consistent with this, EPA has established reference doses for chemicals based on observed cognitive deficits in animal studies (see Table 1 above). Cognitive deficits, including in the range observed in fluoridated areas, are a sufficiently severe effect on human health to warrant prevention, as EPA has recognized in other contexts.

E. Uncertainties

222. Uncertainties are a pervasive aspect of risk assessment; their existence does not negate a finding of risk. As would be expected, there are uncertainties in the fluoride dataset, arising in part from methodological limitations in the available animal studies (e.g., lack of control for litter effects, lack of blinding, lack of studies on neonatal exposures, lack of chronic experiments, etc.). The impact of these limitations on the observed learning and memory deficits is not yet defined. The clear suggestion from the observed findings, however, is that fluoride causes alterations to the brain and behavior. Further, the uncertainties that remain in the animal data are largely offset by the existence of high-quality prospective studies that have *consistently* detected significant associations between “optimal” fluoride exposures and cognitive deficits. While I understand that EPA’s experts in this case question whether the “causal” relationship between fluoridation and IQ loss has been proven, the *Guidelines* do not require proof of causation; they require sufficient evidence of association.³¹²

223. Another factor weighing in favor of an unreasonable risk finding is that the exposure estimates are more straightforward—and permit greater confidence—than the exposure estimates that EPA has had to extrapolate for other chemicals under TSCA. In its NMP risk evaluation, for example, EPA had to make “assumptions about glove use, glove effectiveness,

³¹² EPA (1998a), p. 53.

duration of contact with NMP, concentration of NMP, and amount of skin surface contact with NMP” in order to come up with estimates of human exposure under the conditions of use.³¹⁵ Estimating exposure to fluoridation chemicals involves much less uncertainty, as the concentration of fluoride in the water is defined (0.7 mg/L), and the EPA has extensive empirical data on water consumption in the U.S. that the Agency has described as “scientifically sound.”

224. Based on the available scientific evidence that now exists on the hazards, exposures, and risks of fluoride ingestion, the widespread addition of fluoridation chemicals to drinking water and processed foods in the United States presents an unreasonable risk to human health.

I declare under penalty of perjury, under the laws of the United States, that the foregoing is true and correct to the best of my knowledge and belief.

Executed on May 20, 2020, in Oak Ridge, Tennessee.

Appendix A

Recent Animal Studies of Fluoride Neurotoxicity (Tables A-1 and A-2)

Table A-1. Summary of animal studies that have investigated neuroanatomical and neurochemical endpoints of fluoride toxicity.

Paper	Animal	Sex	Maturity at Start of Exposure	Length of Exposure	Animals per group
Adebayo et al. 2013	Albino Rats	Male	Post-Weaning ^f	1 week	6
Adedara et al. 2017a & b	Wistar Rats	Male	8 weeks old	45 days	12
Agustina et al. 2018	Wistar Rats	Male	Adults	30 days	8
Akinrinade et al. 2015a & b	Wistar Rats	Male	Adults	30 days	5
Ameeramja et al. 2018	Wistar Albino Rats	Female	2 to 3 months old	30 days	6
Atmaca et al. 2014	Wistar Rats	Male	Post-Weaning ^f	21 days	7
Balaji et al. 2015	Swiss Albino Mice	Female	Adults	30 days	6 (of 7)
Banala and Karnati 2015	Wistar Rats	Both	Prenatal	Prenatal + 14, 21 & 30 days	5
Banji et al. 2013	Wistar Rats	Both	Gestational day 6	Prenatal + 15 days	6
Bartos et al. 2018	Wistar Rats	Female	Prenatal	Prenatal + 21 days	5
Bartos et al 2019	Wistar Rats	Both	Pre-Pregnancy	Prenatal + 21 days	5
Basha and Madhusudhan 2010	Wistar Albino Rats	Both	Pre-Pregnancy	Prenatal + 21 days	6
Basha et al. 2011a & b	Wistar Albino Rats	Both	Multigenerational	Prenatal + 12 weeks (3rd generation)	6
Basha and Sujitha 2012a & b	Wistar Rats	Male	3 months old	1 month	6
Basha and Saumya 2013	Albino Mice	Both	Adults	45 days	6
Bharti and Srivastava 2009	Wistar Rats	Female	Adults	28 days	6
Bharti et al. 2012	Wistar Rats	Female	Adults	7 days	6
Chauhan et al. 2013	Sprague-Dawley Rats	Female	6 months old	3 to 6 weeks	4 (of 8)
Chen et al. 2018a	Sprague-Dawley Rats	Female	Pre-Pregnancy	Prenatal + 6 months	6
Chouhan and Flora 2008	Albino Rats	Male	Adults	10 weeks	6
Chouhan et al. 2010	Wistar Albino Rats	Male	Adults	12 weeks	5-6 (of 6)
Dec et al. 2019	Wistar Rats	Males	Pre-Pregnancy	Prenatal + 90 days	6 (of 12)
Dong et al. 2015	Sprague-Dawley Rats	Both	1 month old	>10 months	30
Dong et al. 2015	Sprague-Dawley Rats	Both	10 months pre-birth	Prenatal + 1, 7, 14, 21, & 28 days	10
Flora et al. 2009	Swiss Mice	Male	Adults	10 weeks	5
Flora et al. 2012	Swiss Mice	Male	Adults	28 weeks	5 (of 12)
Ge et al. 2011	Wistar Albino Rats	Both	Pre-Pregnancy	Prenatal + 20 days	8
Ge et al. 2018	ICR Mice	Both	Pre-Pregnancy	Prenatal + 90 days	6
Güner et al. 2016	Wistar Albino Rats	Both	Adult	Prenatal + 1, 3, & 5 months	5

Table A-1. Summary of animal studies that have investigated neuroanatomical and neurochemical endpoints of fluoride toxicity - *Continued*

Paper	Treatment groups	LOAEL ^b	Specific Effect	Hippocampus?
Adebayo et al. 2013	100 mg/L	100 mg/L	Oxidative stress, reduced brain weight	No
Adedara et al. 2017a & b	6.8 mg/L	6.8 mg/L	Oxidative stress, reduced AChE activity, inflammation, Caspase-3 activity	No
Agustina et al. 2018	2.3, 4.5 & 9 mg/kg/day	4.5 mg/kg/day	Reduced number of Purkinje cells	No
Akinrinade et al. 2015a & b	1 & 5 mg/L	1 mg/L	Oxidative stress, inflammation, neuronal damage	No
Ameeramja et al. 2018	136 mg/L	136 mg/L	Oxidative stress	No
Atmaca et al. 2014	100 mg/L	100 mg/L	Oxidative stress & neuronal degeneration	Yes
Balaji et al. 2015	45 & 90 mg/L	45 mg/L	Inhibition of cholinesterase & increased oxidative stress	No
Banala and Karnati 2015	9 mg/L	9 mg/L	Oxidative stress	No
Banji et al. 2013	9 mg/kg/day	9 mg/kg/day	Oxidative stress	No
Bartos et al. 2018	5 & 10 mg/L (=0.6 & 1.2 mg/kg/d)	5 mg/L	Decreased nicotinic receptors & oxidative stress	Yes
Bartos et al. 2019	5 & 10 mg/L (=0.6 & 1.2 mg/kg/d)	5 mg/L	Increased oxidative stress as reflected by decreased CAT, GPT, and GOT	Yes
Basha and Madhusudhan 2010	50 & 150 mg/L	50 mg/L	Oxidative stress & reduced brain protein content	No
Basha et al. 2011a & b	100 & 200 mg/L	100 mg/L	Oxidative stress, reduced brain weight, and histological changes	Yes
Basha and Sujitha 2012a & b	270 mg/L	270 mg/L	Oxidative stress & decreased acetylcholinesterase activity	No
Basha and Saumya 2013	270 mg/L	270 mg/L	Mitochondrial disturbances & Oxidative stress	No
Bharti and Srivastava 2009	150 mg/L	150 mg/L	Oxidative stress	No
Bharti et al. 2012	150 mg/L	150 mg/L	Decreased acetylcholinesterase activity	No
Chauhan et al. 2013	11.3 mg/kg/day	11.3 mg/kg/day	Oxidative stress	No
Chen et al. 2018a	4.5, 23, 45 mg/L	4.5 mg/L	Impaired synaptogenesis	Yes
Chouhan and Flora 2008	10, 50, & 100 mg/L	100 mg/L ^c	Oxidative stress	No
Chouhan et al. 2010	1, 10, 50 & 100 mg/L	1 mg/L	Oxidative stress, alterations in neurotransmitters, neuronal lesions, & increased AChE activity	No
Dec et al. 2019	23 mg/L	23 mg/L	Evidence of inflammatory processes (reduced activity of cyclooxygenases (COX1 & COX2) and increase in prostaglandins)	Yes
Dong et al. 2015	50 mg/L (adults)	50 mg/L	Decrease in muscarinic nicotinic receptors	No
Dong et al. 2015	50 mg/L (offspring)	50 mg/L	Decrease in muscarinic nicotinic receptors	No
Flora et al. 2009	50 mg/L	50 mg/L	Oxidative stress, alteration in neurotransmitters, DNA damage, increased AChE activity	No
Flora et al. 2012	50 mg/L	50 mg/L	Oxidative stress, neuronal degeneration, DNA damage, Protein interaction	Yes
Ge et al. 2011	100 mg/L (+25 mg/kg in food)	100 mg/L	Alteration in protein expression	No
Ge et al. 2018	50 & 100 mg/L	50 mg/L	Alterations of synapse-related proteins	No
Güner et al. 2016	13.6 & 45 mg/L	13.6 mg/L	Neurodegenerative changes & catalase immunoreactivity	Yes

Table A-1. Summary of animal studies that have investigated neuroanatomical and neurochemical endpoints of fluoride toxicity – *Continued*

Paper	Treatment groups	LOAEL	Specific Effect	Hippocampus?
Hamza et al. 2015	4.7 mg/kg/day	4.7 mg/kg/day	Increased oxidative stress	No
Han et al. 2014	11, 23, and 45	23 mg/L ^c	Altered mRNA expression	Yes
Hassan and Abdel-Aziz 2010	4.7 mg/kg/day	4.7 mg/kg/day	Oxidative stress	No
Inkielwicz-Stepniak and Czarnowski 2010	25 mg/L	25 mg/L	Oxidative stress	No
Jia et al. 2019	6 & 113 mg/L	None	No reduction in neuronal density	No
Jiang et al. 2014a	54 mg/L	54 mg/L	Decreased glutamate levels	Yes
Jiang et al. 2014b	11, 23, and 45 mg/L	11 mg/L	Neuronal degeneration, decreased glucose utilization	Yes
Jiang et al. 2019	23 & 45 mg/L	23 mg/L	Impaired neurogenesis & synaptic plasticity	Yes
Kaur et al. 2009	125 mg/L	125 mg/L	Oxidative stress, alteration in neurotransmitters, & neuronal degeneration	No
Khan et al. 2018	20 mg/L	20 mg/L	Inhibition of AChE and increase in oxidative stress	No
Kinawy 2019	678 mg/L	678 mg/L	Oxidative stress	Yes
Li et al. 2019	68 mg/L	68 mg/L	Altered mRNA expression of anxiety & depression-related genes	Yes
Liu et al. 2010	5 & 50 mg/L	5 mg/L	Reductions in nicotinic receptors & activation of photoho-ERK1/2	No
Liu et al. 2011	5 & 50 mg/L	5 mg/L	Increased apoptosis & phosphorylation	No
Lou et al. 2013	10 & 50 mg/L	10 mg/L	Mitochondrial disturbances in neurons, altered protein expression	No
Ma et al. 2015	23 & 45.6 mg/L	23 mg/L	Increased BDNF expression	Yes
Mansour and Tawfik 2012	4.7 mg/kg/day	4.7 mg/kg/day	Oxidative stress	No
McPherson et al. 2018	10 & 20 mg/L (+ food exposure group)	None	No neuronal damage or glia reactivity	Yes
Nabavi et al. 2012a	270 mg/L	270 mg/L	Oxidative stress	No
Nabavi et al. 2012b	270 mg/L	270 mg/L	Oxidative stress	No
Nabavi et al. 2013	270 mg/L	270 mg/L	Oxidative stress	No
Niu et al. 2009	68 mg/L	68 mg/L	Decreased glutamate levels & altered enzyme activity	Yes
Niu et al. 2014	68 mg/L	68 mg/L	Altered protein expression	Yes
Niu et al. 2015a	11, 23, and 45 mg/L	23 mg/L	Microtubule lesions in neurons	Yes
Niu et al. 2015b	68 mg/L	68 mg/L	Alterations in protein expression	No
Niu et al. 2018a	4.5, 23, and 45 mg/L	4.5 mg/L	Endoplasmic reticulum stress	Yes
Niu et al. 2018b	11, 23, and 45 mg/L	11 mg/L	Myelin damage, and alteration to synaptic structure	Yes

Table A-1. Summary of animal studies that have investigated neuroanatomical and neurochemical endpoints of fluoride toxicity – *Continued*

Paper	Treatment groups	LOAEL	Specific Effect	Hippocampus?
Pal and Sarkar 2014	9 mg/kg/day	9 mg/kg/day	Oxidative stress, inhibited enzymes, altered neurotransmitters, reduced protein content	No
Pan et al. 2015	9 mg/kg/day	N/A ^d	Altered protein expression	Yes
Pereira et al. 2011	45 mg/L	45 mg/L	Alterations in neurotransmitters	Yes
Pulungan et al. 2018	2.3, 4.5 & 9 mg/kg/day	none	No reduction in number of pyramidal cells in medial prefrontal cortex	No
Qian et al. 2013	23 mg/L	23 mg/L	Impaired synaptic plasticity, oxidative stress, altered protein expression	Yes
Reddy et al. 2009	9 mg/kg/day	9 mg/kg/day	Oxidative stress & altered enzyme activity	No
Reddy et al. 2014	9, 27, & 45 mg/L	9 mg/L	Oxidative stress, alterations in neurotransmitters, and immunosuppression	No
Rogalska et al. 2017	4.5 & 23 mg/L	23 mg/L ^c	Increased glucose uptake	Yes
Samanta et al. 2016	5.9 mg/kg/day	5.9 mg/kg/day	Oxidative stress, cellular degeneration, apoptosis	No
Sarkar et al. 2014	9 mg/kg/day	9 mg/kg/day	Oxidative stress, inhibited enzymes, & reduced protein content	No
Shalini and Sharma 2015	10 mg/L	10 mg/L	Oxidative stress, reduced protein content & AChE activity	No
Sharma et al. 2014	120 mg/L	120 mg/L	Oxidative stress & cellular degeneration	Yes
Sharma et al. 2018	54 mg/L	54 mg/L	Oxidative stress and neuronal damage	Yes
Shen et al. 2019	200 mg/L	200 mg/L	Apoptosis and degeneration of nerve cells in spinal cord	No
Sun et al. 2017	45 mg/L	45 mg/L	Altered gene expression & apoptosis	Yes
Sun et al. 2018	11, 23, and 45 mg/L	11 mg/L (Fig 3b)	Altered mRNA expression	Yes
Teng et al. 2018	8.25, 16.5, & 33 mg/L	16.5 mg/L ^c	Elevated calcium in hippocampus	Yes
Trivedi et al. 2007	2.7 & 5.4 mg/kg/day	2.7 mg/kg/day	Reduced protein content	No
Wang et al. 2018a	11, 23, and 45 mg/L	11 mg/L (Fig 4b)	Altered expression of mi-RNAs	No
Wang et al. 2018b	45 mg/L	45 mg/L	Cellular degeneration, DNA damage	Yes
Wei et al. 2018	50 mg/L (adults)	50 mg/L	Neuronal injury (as evident by damage to Nissl bodies)	No
Wei et al. 2018	50 mg/L (offspring)	50 mg/L	Neuronal injury (as evident by damage to Nissl bodies)	No
Yan et al. 2016	60 & 120 mg/L	60 mg/L	Increased apoptosis & inflammation	Yes
Yang et al. 2018a	60 & 120 mg/L	60 mg/L	Apoptosis, altered protein expression, increased inflammation	Yes
Yu et al. 2019	2.3 & 13.6 mg/L	2.3 mg/L	Alterations of L-type calcium channels	Yes
Yuan et al. 2019	23, 45, 68 mg/L	23 mg/L	Reduced brain protein content, impaired insulin signaling pathway, reduced brain organ coefficient	Yes
Zhang et al. 2013a	45 mg/L	45 mg/L	Oxidative stress, neuronal loss, altered protein expression	Yes
Zhang et al. 2015a	5 & 50 mg/L	5 mg/L	Increased oxidative stress & activation of AGE/RAGE Pathway	Yes

Table A-1. Summary of animal studies that have investigated neuroanatomical and neurochemical endpoints of fluoride toxicity – *Continued*

Paper	Treatment groups	LOAEL	Specific Effect	Hippocampus?
Zhang et al. 2017a	45 mg/L	45 mg/L	Impaired synaptic plasticity	No
Zhang et al. 2019	25, 50, 100 mg/L	50 mg/L ^e	Autophagy in hippocampus	Yes
Zhao et al. 2019	4.5, 23, 45 mg/L	4.5 mg/L [Fig 6e]	Mitochondrial disturbances	Yes
Zheng et al. 2016	45 mg/L	45 mg/L	Increased apoptosis	Yes
Zhou et al. 2019	4.5, 23, 50 mg/L	23 mg/L ^c	Decreased neurons, suppressed autophagy, and enhanced apoptosis in hippocampus	Yes
Zhu et al. 2011 & Zhang et al. 2011	7, 13.6, & 27 mg/L	13.6 mg/L ^c	Decrease in synaptic membrane fluidity & increased calcium	Yes
Zhu et al. 2017	34 mg/L	34 mg/L	Altered protein expression in ERK/CREB signaling pathway	Yes

^a Where the study does not identify the sex of the animals, it is assumed that both sexes were studied.

^b A LOAEL refers to the lowest observed adverse effect level where a statistically significant result was observed.

^c At least one effect was seen at lower treatment doses (as reflected by a visually apparent dose-related trend), but the effect(s) at the lower treatment levels did not reach statistical significance.

^d The authors did not perform a statistical analysis to determine if the observed changes were statistically significant.

^e Ultrastructural observations of the rat hippocampal CA1 cells identified changes in the 25 mg/L group (i.e., increased lipofuscin content), but a statistical analysis of these changes was not performed.

^f Where the study does not identify the age of the animal at the start of the experiment, it is assumed that the animals had already completed weaning.

Zheng et al. 2016	45 mg/L	Morris Water Maze / Open Field	45 mg/L
Zhou et al. 2019	4.5, 23, & 45 mg/L	Morris Water Maze	23 mg/L ^c
Zhu et al. 2017	45 mg/L (8 to 11 mg/kg/day)	Morris Water Maze	45 mg/L

^a Where the study does not identify the sex of the animals, it is assumed that both sexes were studied.

^b A LOAEL refers to the lowest observed adverse effect level where a statistically significant result was observed.

^c At least one effect was seen at lower treatment doses (as reflected by a visually apparent dose-related trend), but the effect(s) at the lower treatment levels did not reach statistical significance.

^d At least one statistically significant effect was seen at lower treatment doses but for a neurological endpoint that is not specific to learning or memory impairments.

^e The effect in the fluoride + lead treatment group was statistically significant, but the effect in the fluoride-only treatment group did not reach statistical significance.

^f A statistically significant effect was observed in the low treatment dose group (5 mg/kg/day) when compared to the control, but there were no significant differences between the control and mid/high dose treatment groups (10 mg/kg/day & 20 mg/kg/day).

^g Where the study does not identify the age of the animal at the start of the experiment, it is assumed that the animals had already completed weaning

Appendix B

KATHLEEN M. THIESSEN, Ph.D.
Senior Scientist
Oak Ridge Center for Risk Analysis, Inc.

Education

Ph.D. 1986 Genetics, University of Tennessee-Oak Ridge, Graduate School of Biomedical Sciences, Oak Ridge, TN
B.A. 1981 Biology and Chemistry (*Summa cum laude*), Covenant College, GA

Capabilities

Health Effects Assessment
Dose and Risk Assessment
Analysis of Environmental Transport and Exposure Pathways
Uncertainty and Sensitivity Analysis
Technical Writing/Editing, Technical and Public Presentations

Experience Summary

Dr. Thiessen is experienced in the evaluation of exposures, doses, and risks to human health from trace levels of contaminants in the environment and in the use of uncertainty analysis for environmental and health risk assessment. She has served on two National Research Council subcommittees, one charged with the review of fluoride exposure and toxicology, and one dealing with guidance levels for air contaminants (including hydrogen fluoride) in submarines. Dr. Thiessen has also written two reports for the U.S. Environmental Protection Agency, one on the health effects of hydrogen fluoride and related compounds, and one on the health effects of mercuric chloride. Dr. Thiessen has led several working groups on urban contamination and dose reconstruction for the International Atomic Energy Agency's programs on environmental transport modeling and has served on the coordinating committees of the programs; she currently leads a working group on assessment of exposures and countermeasures in urban environments. She also serves on a committee for the preparation of a new International Atomic Energy Agency report on modeling the impacts of planned discharges or radioactivity, and she is involved in the preparation of an IAEA guidance document on implementation of remediation strategies following accidental releases of radioactivity. Dr. Thiessen participated in two symposia on reconstruction of internal doses from Fukushima releases organized by Japan's National Institute of Radiological Sciences, and she has served as a consultant on environmental modeling issues to the Korea Atomic Energy Research Institute and on uncertainty analysis to the National Council on Radiation Protection and Measurements. Dr. Thiessen contributed to the development of a risk-based screening approach to prioritize further investigation of contaminants and exposure situations in various assessment contexts, and she led in the application of risk-based screening techniques for the reconstruction of doses and health risks associated with releases of chemicals and radionuclides from the U.S. Department of Energy's Oak Ridge (Tennessee) facilities. Dr. Thiessen also led an analysis of human exposures, doses, and health risks to off-site individuals associated with historic releases of radionuclides to the Clinch River from the Oak Ridge facilities.

Experience

- 1992-present Senior Scientist and Director, Oak Ridge Center for Risk Analysis, Inc. (Formerly *SENES* Oak Ridge, Inc., Center for Risk Analysis), Oak Ridge, TN.
- Review of data on contaminant exposure and toxicology.
 - Analysis of environmental transport and exposure pathways.
 - Screening techniques for environmental assessment.
 - Dose reconstruction.
 - Uncertainty analysis for environmental assessment.
 - International model validation using Chernobyl data sets.
 - Working Group Leader for International Atomic Energy Agency research programs.
 - Project coordination.
 - Technical review.
- 1991-1992 Consultant and Technical Writer. Environmental Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN.
- 1987-1992 Lecturer in Genetics. University of Tennessee, Oak Ridge Graduate School of Biomedical Sciences.
- 1986-1989 Oak Ridge National Laboratory, Health and Safety Research Division, Chemical Hazard Evaluation Program.
- Assessment of health effects from chemicals.
 - Risk assessment.
 - Technical review.

THE WORLD-WIDE MOVEMENT AGAINST WATER FLUORIDATION

In stark contrast to the Center for Disease Control's claim that fluoridation is one of the top ten public health achievements of the 20th century, it is **one of the most widely rejected health interventions in the world.**

Out of 196 nations, only 24 have any fluoridation, and only 10, like the U.S., for more than half their population. Over 95% of the world's population is fluoridation-free. The U.S. fluoridates as many people as the rest of the world combined.

None of the largest Asian nations, including China, India and Japan, fluoridate. Out of 54 countries in Africa, only one fluoridates – Libya, and only for a small percent of its population. In Europe, only four out of 48 countries fluoridate (less than 2% of the population). A few have fluoridated salt, but only as a consumer choice.

France, Germany, Belgium, the Netherlands, Denmark, Norway and Sweden have all prohibited fluoridation, many citing the ethical problem of putting any drug in drinking water.

For dozens of nations that haven't banned it, thousands of major cities and smaller towns don't fluoridate, including **Athens, Barcelona, Budapest, Geneva, Helsinki, London, Madrid, Prague, Rome, Vienna and Warsaw**. Ireland is the only European nation mandating fluoridation. But despite the mandate, 13 town and county councils, including Dublin and Cork, have voted for its immediate cessation.

Many organizations still support fluoridation, but **those opposing it grows year by year**. They include:

- American Academy of Environmental Medicine • Center for Health, Environment and Justice
- Children's Health Defense • Eau Secours (Canadian coalition of 234 groups promoting clean, safe water)
- Council of Canadians • Environmental Working Group • Food and Water Watch
- * Institute of Neurotoxicology & Neurological Disorders • International Academy of Biological Dentistry and Medicine
- International Academy of Oral Medicine and Toxicology • League of United Latin American Citizens
- Moms Against Fluoridation • Organic Consumers Association

In addition, **many organizations once endorsing fluoridation have pulled back**, no longer taking a position. They include the Alzheimer's Association, American Academy of Allergy, Asthma and Immunology, Center for Science in the Public Interest, Consumers Union (Consumer Reports), National Association of Social Workers, National Down Syndrome Congress, National Down Syndrome Society and National Kidney Foundation.

The trend is clear. And as the scientific data accumulate, more and more nations, cities and organizations are challenging the safety, efficacy, costs and ethics of fluoridation.

Community water fluoridation
Urinary fluoride
Attention deficit hyperactivity disorder (ADHD)
Canadian Health Measures Survey (CHMS)

ABSTRACT

Background: Exposure to fluoride has been linked with increased prevalence of attention deficit hyperactivity disorder (ADHD) in the United States and symptoms of inattention in Mexican children. We examined the association between fluoride exposure and attention outcomes among youth living in Canada.

Method: We used cross-sectional data collected from youth 6 to 17 years of age from the Canadian Health Measures Survey (Cycles 2 and 3). Urinary fluoride concentration adjusted for specific gravity (UF_{SG}) was available for 1877 participants. Water fluoride concentration measured in tap water samples was available for 980 participants. Community water fluoridation (CWF) status was determined by viewing reports on each city's website or contacting the water treatment plant. We used logistic regression to test the association between the three measures of fluoride exposure and ADHD diagnosis. Linear regression was used to examine the relationship between the three measures of fluoride exposure and the hyperactivity/inattention score on the Strengths and Difficulties Questionnaire (SDQ).

Results: UF_{SG} did not significantly predict ADHD diagnosis or hyperactive/inattentive symptoms. A 1 mg/L increase in tap water fluoride level was associated with a 6.1 times higher odds of an ADHD diagnosis (95% CI = 1.60, 22.8). A significant interaction between age and tap water fluoride level ($p = .03$) indicated a stronger association between tap water fluoride and hyperactivity/inattention symptoms among older youth. A 1 mg/L increase in water fluoride level was associated with a 1.5 SDQ score increase (95% CI: 0.23, 2.68, $p = .02$) for youth at the 75th percentile of age (14 years old). Similarly, there was a significant interaction between age and CWF. At the 75th percentile of age (14 years old), those living in a fluoridated region had a 0.7-point higher SDQ score (95% CI = 0.34, 1.06, $p < .01$) and the predicted odds of an ADHD diagnosis was 2.8 times greater compared with youth in a non-fluoridated region (aOR = 2.84, 95% CI: 1.40, 5.76, $p < .01$).

Discussion: Exposure to higher levels of fluoride in tap water is associated with an increased risk of ADHD symptoms and diagnosis of ADHD among Canadian youth, particularly among adolescents. Prospective studies are needed to confirm these results.

1. Introduction

Fluoride is beneficial in the prevention of dental caries (Health Canada, 2010). It can naturally occur in water, but often at levels that are too low to prevent tooth decay. In the middle of the 20th century, the concept of adding fluoridation chemicals (usually hexafluorosilicic acid) to water supplies was introduced. Currently, approximately 38% of Canadians on public water supplies receive community water fluoridation (CWF; Public Health Agency of Canada, 2017) compared with 74% of Americans and only 3% of Europeans (Centers for Disease Control and Prevention, 2014). Consumption of optimally fluoridated

water (i.e., 0.7 mg fluoride per liter of water) accounts for approximately 40 to 70% percent of daily fluoride ingestion (United States Environmental Protection Agency, 2010).

Fluoride has been classified as a developmental neurotoxin (Grandjean and Landrigan, 2014) – a claim that is uncontested at high exposure levels, but remains debated at the exposure levels associated with water fluoridation. Epidemiological studies conducted in endemic fluorosis areas (i.e., naturally occurring water fluoride concentrations > 1.5 mg/L) have reported a negative association between fluoride concentrations in drinking water and intellectual ability in children (Das and Mondal, 2016; Rocha-Amador et al., 2007; Seraj

et al., 2012; Xiang et al., 2003; Zhao et al., 1996). A meta-analysis of 27 studies concluded that children who lived in areas with high fluoride exposure had IQ scores that were approximately seven points lower than those who lived in low-exposure areas (Choi et al., 2012). Most of the studies included in this review were cross-sectional and had deficient reporting of key information; however, the consistency of their findings supports the potential for fluoride-mediated developmental neurotoxicity at elevated levels of exposure. Recently, three longitudinal birth cohort studies addressed these limitations by examining the associations between maternal fluoride exposure indicators in pregnancy and offspring cognitive abilities. These prospective studies reported a negative association between prenatal fluoride exposure and cognitive development in infants (Jiménez et al., 2017), children living in Mexico (Bashash et al., 2017), and children living in Canada (Green et al., 2019).

Experimental and epidemiologic studies have also reported an association between early-life fluoride exposure and adverse behavioural outcomes. One study demonstrated that prenatal fluoride exposure caused greater hyperactivity in male rat pups whereas females were more sensitive to postnatal exposures (Mullenix et al., 1995). In an ecological study, higher prevalence of water fluoridation was associated with increased prevalence of Attention Deficit Hyperactivity Disorder (ADHD) diagnoses among youth in the United States (Malin and Till, 2015). In a cohort study, higher levels of fluoride exposure during pregnancy were associated with more inattentive symptoms and total ADHD symptoms in Mexican children aged 6 to 12 years (Bashash et al., 2018). In contrast, a study using data from the Canadian Health Measures Survey (CHMS; Statistics Canada, 2013; 2015) did not report an association between urinary fluoride corrected for dilution and a diagnosis of a learning disability in children aged 3 to 12 years (Barberio et al., 2017).

We examined the relationship between urinary and tap water fluoride concentrations and attention-related outcomes in a national sample of Canadian youth aged 6 to 17 years. We hypothesized that higher levels of urinary and water fluoride would be associated with increased odds of an ADHD diagnosis and more symptoms of hyperactivity and inattention.

2. Methods

2.1. Data source and participants

We used data from Cycle 2 (2009–2011) and Cycle 3 (2012–2013) of the CHMS collected by Statistics Canada. All aspects of the CHMS were reviewed and approved by Health Canada's Research Ethics Board (Day et al., 2006); the current study was approved by the York University Research Ethics Board.

The CHMS randomly selected participants aged 3 to 79 years who lived in private households across Canada. A total of 6395 people participated in Cycle 2 of the CHMS, with 2520 people providing urine samples analyzed for fluoride concentration. Among those who provided urine samples, 909 (36%) were between 6 and 17 years of age. For Cycle 3, a total of 5785 people were enrolled, with 2667 people providing urine samples analyzed for fluoride concentration; 968 (36%) were between 6 and 17 years of age. In Cycle 3 only, 980 youth ages 6 to 17 were selected to provide a tap water sample to be analyzed for fluoride content. Full details about the survey can be found at www.statcan.gc.ca.

Approximately half of the sites included in Cycles 2 and 3 received CWF, which was determined by viewing reports on each city's website or contacting the water treatment plant (see Supplemental Table 1). In total, 13 of 25 sites received CWF (eight from Cycle 2 and five from Cycle 3), corresponding to approximately 1400 (51.9%) of 2700 participants included in the study (rounded due to Statistics Canada data release requirements). Nine additional sites were considered to have mixed fluoridation status, corresponding to approximately 650 (24.0%)

participants. A site was classified as mixed for one of five reasons: unclear site boundaries ($n = 150$), having some municipalities within the site add fluoride while others did not ($n = 250$), and stopping CWF during the period spanning CHMS data collection ($n = 50$). We excluded all mixed sites from any analysis using city fluoridation status as a variable. We also excluded sites which were labeled as fluoridated or non-fluoridated, but had an average water fluoride level that was either 2.5 times lower ($n = 100$) or higher ($n = 100$) than other fluoridated or non-fluoridated sites, respectively.

We utilized three participant samples for our analyses; see Fig. 1 for a participant flow chart. The first sample, collapsed across both cycles, included 1877 youth ages 6 to 17 who had urinary fluoride measurements. The second sample categorized 1722 youth who were on a municipal water system (instead of a well) as either living in a fluoridated region ($n = 932$; 54.1%) or a non-fluoridated region ($n = 790$; 45.9%). This sample only included youth who primarily drank tap water (instead of bottled water), did not have a home filtration system that removes fluoride (i.e., reverse osmosis or distillation), and have lived in their current residence for three or more years. The third sample consisted of 710 youth from Cycle 3 who primarily drank tap water (instead of bottled water) and had fluoride levels measured in their tap water.

2.2. Measurement of urinary fluoride concentration

Urine spot samples were collected under normal (non-fasting) conditions and were not standardized with respect to collection time. Fluoride concentrations in spot urine samples were analyzed using an Orion PH meter with a fluoride ion selective electrode after being diluted with an ionic adjustment buffer (Statistics Canada, 2013). Urinary analyses were performed at the Human Toxicology Laboratory of the Institut National de Santé Publique du Québec (INSPQ; accredited under ISO 17025) under standardized operating procedures (Statistics Canada, 2013; 2015). The precision and accuracy of the fluoride analyses, including quality control measures and quality assurance reviews, are described in previous publications (Health Canada, 2015). The limit of detection (LoD) for urinary fluoride was 20 µg/L for Cycle 2 and 10 µg/L for Cycle 3 (Health Canada, 2015). No urinary fluoride values in the Cycle 2 or Cycle 3 samples were below the LoD. Urinary fluoride concentrations were adjusted for specific gravity (UF_{SG} ; mg/L); specific gravity shows no systematic variation within a day and is less dependent on body size, age, and gender than creatinine (Barr et al., 2005; Nermell et al., 2008; Moriguchi et al., 2005; Suwazono et al., 2005).

2.3. Measurement of water fluoride concentration

Tap water samples were collected at respondents' homes and were available for Cycle 3 only. Samples were analyzed for fluoride concentrations (mg/L) via a basic anion exchange chromatography procedure with a LoD of 0.006 mg/L. Concentrations at the LoD were assigned a missing value code by Statistics Canada, and these values were subsequently replaced with an imputed value of $LoD/\sqrt{2}$ (Hornung and Reed, 1990); 150 of 980 (16%) water samples had fluoride levels below the LoD.

2.4. Measurement of attention-related outcomes

Primary outcomes included the hyperactivity/inattention subscale score from the Strengths and Difficulties Questionnaire (SDQ; Goodman, 2001) and a physician-made diagnosis of ADHD; these outcomes were measured in both Cycles 2 and 3. Data are presented for youth ages 6 to 17 because the SDQ was only administered to youth under age 18 and 90% of youth with ADHD are diagnosed after age 6 (Kessler et al., 2005). For children aged 6 to 11 years, information about ADHD diagnosis and SDQ ratings were provided by parents or guardians, whereas youth aged 12 to 17 years completed the questionnaire

Fig. 1. Subject inclusion in each regression analysis.

themselves, including the question about having a diagnosis of ADHD.

The SDQ consists of 25 items with a 3-point response scale (0 = *not true*, 1 = *somewhat true*, and 2 = *certainly true*). These items are divided among five subscales: emotional problems, conduct problems, hyperactivity-inattention, peer problems, and prosocial behaviour. Possible scores on each subscale range from 0 to 10. The five-item hyperactivity-inattention subscale was used in the current study to test the association between fluoride and ADHD-like symptoms.

The item pertaining to a physician-made diagnosis of ADHD differed between Cycles 2 and 3. In Cycle 2, respondents were asked *Do you have a learning disability?*, and if they responded *yes*, they were asked to specify the type of learning disability from among four options: (1) Attention Deficit Disorder, no hyperactivity [ADD]; (2) Attention Deficit Hyperactivity Disorder [ADHD]; (3) Dyslexia; and (4) Other. In Cycle 3, parents of children aged 6 to 11 were asked directly whether their child had ADHD, and if so, which subtype. Similarly, youth age 12 or older were asked whether they have received a physician-diagnosis of ADHD, and if so, which subtype. Across both cycles, all subtypes were combined into a single dichotomous variable of ADHD diagnosis (*no* = 0, *yes* = 1) as per current diagnostic classification schemes (American Psychiatric Association, 2013).

2.5. Covariates

Covariates related to ADHD diagnosis and to fluoride metabolism were selected based on literature review and consultation with an ADHD expert. The following covariates were included in each regression model: sex, age of child at household interview, ethnicity (white or ethnic minority), Body Mass Index (BMI), highest level of education obtained by either parent (less than a bachelor's degree vs. bachelor's degree or greater), total household income (Canadian dollars), exposure to cigarette smoke inside the home (yes or no), and $\log_{10}$ -transformed value of concurrent level of blood lead ($\mu\text{g}/\text{dL}$).

2.6. Statistical analysis

Outliers that had high Studentized residuals, leverage, or Cook's distance values were removed from all analyses with UF_{SG} as a predictor; these outliers (0.27% of values) represented individuals with urinary fluoride levels that were over 30 times the mean UF_{SG} level, likely representing an acute fluoride ingestion (e.g., swallowing toothpaste). Further, individuals with the highest incomes were identified as extreme observations; these values were replaced with the next highest income value (only 0.01% of income values were adjusted).

We used robust logistic regression to examine the associations between each fluoride exposure measure (UF_{SG} , CWF status, tap water

fluoride) and ADHD diagnosis with the same set of covariates in each model. Box-Tidwell tests were used to check the linearity of the relationship between the log-odds of the dependent variable (ADHD diagnosis) and all continuous predictors; none of the non-linear terms were significant. Next, we used robust linear regression models with the same set of covariates to examine the associations between the three measures of fluoride exposure and the SDQ hyperactivity/inattention subscale score. Because the regression models produced heteroscedastic and non-normal residuals, all significance tests and confidence intervals were based on robust Huber-White standard errors. No issues with multicollinearity were detected from variance inflation factor (VIF) statistics. All regression analyses tested interactions between age and fluoride and between sex and fluoride, as hyperactivity is more common in younger boys and sex-dependent fluoride effects have been previously reported (Mullenix et al., 1995; Green et al., 2019). If an interaction with age was significant, we probed the interaction by calculating the predicted association between fluoride and the outcome at the 25th and 75th percentiles of age. When a tested interaction was non-significant, the model was re-estimated without the interaction term and the overall associations were interpreted. Finally, we conducted sensitivity analyses to test whether the associations between the fluoride exposure variables and ADHD diagnosis differed between cycles given that the question about ADHD diagnosis was posed differently across the two cycles. A two-tailed $\alpha = 0.05$ was used as the threshold for statistical significance.

3. Results

3.1. Descriptive statistics

Of all variables included in the CHMS, missing data were highest for household income (missing among 29% and 23% of CHMS respondents in Cycle 2 and 3, respectively); however, Statistics Canada provided imputed estimates for all participants missing the household income variable. Across Cycle 2 and 3 combined, most demographic variables (including sex, age, ADHD diagnosis, SDQ score, and length of residence) had less than 2% missing data. For highest household education, 2.6% of data were missing, and 7.4% of participants did not report their height or weight, which are needed to calculate BMI.

Table 1 presents descriptive statistics for the different samples used for the regression models. Among the 1877 youth in Cycles 2 and 3 with a urinary fluoride measurement, 51.2% were male, 72.6% were white, and 47.0% had at least one parent with a university degree or higher. In this sample, 137 (7.3%) reported having received a diagnosis of ADHD; the mean for the SDQ Hyperactivity-Inattention subscale score was 2.7 ($SD = 2.7$; range: 0 to 10) with 201 (11.4%) youth having scores in the clinical range (i.e., above 90th percentile; Goodman, 2001). As expected, participants with an ADHD diagnosis had significantly higher scores on the SDQ Hyperactivity-Inattention subscale ($M = 6.5$, $SD = 2.5$) than those without a diagnosis ($M = 2.5$, $SD = 2.4$), $t = 24.8$, $p < .01$. Table 2 provides descriptive statistics for the 1877 youth aged 6 to 17 years with and without an ADHD diagnosis.

3.2. Fluoride measurements

The mean UF_{SG} concentration was 0.61 mg/L ($Mdn = 0.51$; $SD = 0.39$; 10th to 90th percentile range = 0.27–1.06 mg/L) among the 1877 youth from Cycles 2 and 3. Mean UF_{SG} concentration was significantly higher among youth who lived in communities with fluoridated drinking water ($M = 0.82$ mg/L, $SD = 0.54$) than among youth who lived in communities without fluoridated drinking water ($M = 0.46$ mg/L, $SD = 0.32$), $t = 15.1$, $p < .01$. The mean water fluoride concentration was 0.23 mg/L ($Mdn = 0.12$; $SD = 0.24$; 10th–90th percentile = 0.01–0.65 mg/L) among the 710 youth for whom tap water measures were available, excluding those who reported drinking bottled water as their main source of water. As expected, water fluoride

levels were significantly higher among those living in a fluoridated region ($M = 0.49$ mg/L, $SD = 0.22$) than non-fluoridated region ($M = 0.04$ mg/L, $SD = 0.06$), $t = 34.9$, $p < .01$. Table 3 presents the urinary fluoride and water fluoride levels across demographic characteristics, fluoride exposure variables, and attention outcomes.

3.3. Association between fluoride exposure and ADHD diagnosis

No planned interactions were significant in the logistic regression of ADHD diagnosis on UF_{SG} concentration; thus, the final model did not include interaction terms. UF_{SG} did not significantly predict an ADHD diagnosis (adjusted Odds Ratio [aOR] = 0.96; 95% CI: 0.63, 1.46, $p = .84$) adjusting for covariates (Table 4). In the regression of ADHD diagnosis on CWF, there was a significant interaction between age and CWF ($B = 0.19$, $p = .02$), such that the association between CWF and the odds of an ADHD diagnosis was stronger among older youth. Specifically, at the 75th percentile of age (14 years old), the predicted odds of an ADHD diagnosis was 2.8 times greater among youth in a fluoridated region compared with youth in a non-fluoridated region (aOR = 2.84, 95% CI: 1.40, 5.76, $p < .01$), whereas among youth at the 25th percentile of age (9 years old), the predicted odds of an ADHD

[†] Cycle 3 only.

diagnosis was similar across CWF status (aOR = 0.91, 95% CI: 0.41, 1.99, $p = .81$; Table 4). Finally, tap water fluoride concentration was significantly associated with having an ADHD diagnosis, adjusting for covariates; this effect did not significantly interact with sex or age. Specifically, a 1 mg/L increase in tap water fluoride was associated with a 6.1 times higher odds of ADHD diagnosis (95% CI: 1.60, 22.8, $p < .01$; Table 4).

Estimating the models with UF_{SG} and CWF for Cycle 2 and 3 separately showed a similar pattern (Supplemental Table 2). For the regression with CWF, the interaction with age was not significant using Cycle 2 data only ($B = 0.12$, $p = .35$), but was significant using data from Cycle 3 only ($B = 0.30$, $p = .03$).

3.4. Association between fluoride exposure and SDQ hyperactive/inattentive scores

No planned interactions were significant in the regression of SDQ hyperactive/inattentive subscale scores on UF_{SG} concentration; thus, the final model did not include interaction terms. UF_{SG} did not significantly predict SDQ hyperactive/inattentive subscale scores ($B = 0.31$, 95% CI = -0.04 , 0.66, $p = .08$; Table 4).

Next, there was a significant interaction between age and CWF status ($B = 0.11$, $p = .01$) such that the association between CWF and hyperactivity/inattention scores was stronger among older youth. Specifically, the regression model predicted that for youth at the 75th percentile of age (14 years old), living in a fluoridated region was associated with a 0.7-point higher SDQ hyperactivity/inattention score (95% CI = 0.34, 1.06, $p < .01$). In contrast, among youth at the 25th percentile of age (9 years old), CWF status was not significantly associated with SDQ hyperactivity/inattention scores ($B = 0.04$, 95% CI = -0.38 , 0.46, $p = .85$).

75th percentile age	2.84*	1.40, 5.76	0.70*	0.34, 1.06
25th percentile age	0.91	0.41, 1.99	0.04	-0.38 , 0.46

Abbreviations: ADHD = Attention Deficit/Hyperactivity Disorder; CWF = community water fluoridation; aOR = adjusted odds ratio; SDQ H/I = Strengths and Difficulties Questionnaire Hyperactivity-Inattention.

* $p < .05$.

^a Adjusted for child's sex, age at interview, ethnicity (white or other), body mass index, highest level of parental education, total household income, exposure to cigarette smoke inside the home (yes/no), concurrent blood lead level (log₁₀-transformed).

^b Non-significant main effect of urinary fluoride level predicting ADHD diagnosis ($B = -0.04$, $p = .84$) or SDQ subscale score ($B = 0.31$, $p = .08$).

^c Interaction between age and water fluoride level predicting SDQ subscale score ($B = 0.31$, $p = .03$).

^d Since the interaction between age and water fluoride was not significant, only the main effects are presented for the logistic regression predicting ADHD diagnosis from fluoride in tap water (mg/L).

^e Significant interaction between age and CWF status predicting ADHD diagnosis ($B = 0.19$, $p = .03$) and SDQ subscale score ($B = 0.11$, $p = .01$).

Finally, the interaction between age and tap water fluoride level was also significant ($B = 0.31$, $p = .03$) such that the association between tap water fluoride and SDQ hyperactivity/inattention score was

stronger among older youth. In particular, among youth at the 75th percentile of age (14 years old), an increase of 1 mg/L in water fluoride level was associated with a 1.52 increase in the SDQ hyperactivity/inattention subscale score (95% CI: 0.23, 2.68, $p = .02$). However, for youth at the 25th percentile of age (8 years old), the association between water fluoride level and SDQ hyperactivity/inattention subscale score was not significant ($B = -0.33$, 95% CI: $-1.51, 0.84$, $p = .58$).

4. Discussion

We found that Canadian youth exposed to higher tap water fluoride levels had a higher risk of receiving an ADHD diagnosis and reported more symptoms of hyperactivity and inattention. Specifically, an increase of 1.0 mg/L in water fluoride concentration was associated with a 6.1 times higher odds of an ADHD diagnosis after accounting for potential confounding variables, such as exposure to second-hand smoke, household income, and blood lead level. Likewise, water fluoride concentration was positively associated with hyperactive/inattentive symptoms, especially among older youth. To contextualize these results, the difference in water fluoride concentration between cities with and without fluoridation is approximately 0.5 mg/L. Our finding of a 1.5-point increase in the SDQ hyperactive/inattentive symptom subscale for each increase of 1 mg/L in water fluoride level implies a 0.75-point increase per 0.5 mg/L water fluoride; this result is remarkably consistent with our finding of a 0.7-point increase on the SDQ's hyperactivity/inattention subscale observed among older youth living in a fluoridated versus non-fluoridated region.

In contrast, urinary fluoride levels were not significantly associated with a diagnosis of ADHD or hyperactive/inattentive symptoms. Water fluoride concentration and CWF status may be more strongly associated with attention-related outcomes than urinary fluoride levels because fluoride concentrations in municipal water supplies vary within a limited range and therefore may serve as a proxy for early-life and chronic fluoride exposure. In contrast, urinary fluoride levels in spot samples are more likely to fluctuate due to the rapid elimination kinetics of fluoride. Additionally, urinary fluoride values may capture acute exposures due to behaviours that were not controlled in this study, such as professionally applied varnish, consumption of beverages with high fluoride content (e.g., tea), or swallowing toothpaste prior to urine sampling. Finally, the association between urinary fluoride and attention-related outcomes could be obscured due to reduced fluoride excretion (i.e., increased fluoride absorption) during a high growth spurt stage (Jha et al., 2011; World Health Organization, 1997). Despite these limitations, use of individualized biomarkers is considered an improvement over past ecologic studies (Malin and Till, 2015) examining the association between ADHD and fluoride exposure and it has the advantage of examining all sources of fluoride exposure, not just from drinking water.

Our findings are consistent with earlier studies showing a relationship between fluoride exposure and ADHD. In particular, Malin and Till (2015) found that a 1% increase in community water fluoridation prevalence in 1992 was associated with approximately 67,000 to 131,000 additional ADHD diagnoses from 2003 to 2011 among children and adolescents in the United States. Conversely, Barberio and colleagues (2017) did not find a significant relationship between fluoride exposure and learning disabilities (including ADHD) using data from the CHMS Cycles 2 and 3. A direct comparison of our results to the results found by Barberio and colleagues is challenged by the differences in how the data were analyzed between the two studies. Our sample included youth between ages 6 and 17, whereas Barberio and colleagues restricted their sample to youth ages 3 to 12. Further, Barberio and colleagues included participants with learning disabilities instead of selecting only those with a diagnosis of ADHD. Finally, the current study accounted for whether youth in both Cycles 2 and 3 drank unfiltered municipal tap water. It may be that the effects of fluoride exposure are most pronounced in older youth, or that fluoride is

specifically associated with ADHD-related behaviours as opposed to learning disabilities. Finally, inclusion of learning disabilities may also introduce selection bias due to differences in how learning disabilities and ADHD are diagnosed in Canada.

Our findings showed that age modified the association between fluoride exposure and the likelihood of ADHD diagnosis and symptoms of hyperactivity and inattention, such that the associations were stronger among older youth. The method used in the CHMS may not be as sensitive for young children who are at risk of an ADHD diagnosis but have not yet been diagnosed; given that 90% of youth with ADHD are diagnosed after age 6 (Kessler et al., 2005), we restricted our minimum age to 6 years. Cumulative exposure to fluoride over time may also impact neurobehavioural development such that youth show more symptoms as they age. Alternatively, because the developing brain is highly sensitive to environmental toxins (Grandjean and Landrigan, 2006; 2014) and because gene expression later in life is impacted by epigenetic changes that occur earlier in development (Roth, 2012), changes produced by early exposure to environmental toxins may manifest later in development.

While ADHD is known to have a strong genetic component with an estimated heritability of 70% to 80% (Larsson et al., 2014), environmental risk factors are also believed to contribute to the development of ADHD. Prenatal substance exposures, heavy metal and chemical exposures, and nutritional factors have been proposed to contribute to the rise in ADHD in the United States (Xu et al., 2018; Sciberras et al., 2017) and an increase in behavioural difficulties as assessed by the SDQ (Philippat et al., 2017; Oulhote et al., 2016; Luk et al., 2018). A recent systematic review (Donzelli et al., 2019) reported a significant association between lead exposure and risk of ADHD in 12 out of 17 studies; the adjusted odds ratios ranged from 1.09 to 7.25, which is within the range of the current study findings. Although the precise mechanism by which fluoride affects neurodevelopment is unclear, several possible mechanisms have been proposed. Animal studies have shown alterations in acetylcholine or cholinergic receptors due to fluoride exposure (Chouhan et al., 2010; Liu et al., 2010; Reddy et al., 2014). In particular, both nicotinic acetylcholine receptors and cholinesterase expression appear to play a role in attentional processes (Levin et al., 2011). Other studies have shown morphological changes in neurons (Bhatnagar et al., 2011), mitochondria (Zhao et al., 2019), increased catalase immunoreactivity (Güner et al., 2016), more oxidative stress (Zhang et al., 2015), and increases in apoptotic neurons and abnormal mitochondrial dynamics (Lou et al., 2013, 2014). Further, some studies have suggested that fluoride may suppress thyroid function (Trabelsi et al., 2001); subclinical hypothyroidism during pregnancy has been linked with increased risk for attention disorders (Modesto et al., 2015; Pääkkilä et al., 2014).

Our study has some limitations. First, tap water fluoride was measured in Cycle 3 only, which decreased the sample size for analyses using this predictor. However, we were able to determine CWF status for participants in both Cycle 2 and 3, which permitted examining the concordance between the effects associated with tap water fluoride level, CWF status, and urinary fluoride level. Second, use of exposure metrics obtained at the same time as the outcome of interest (cross-sectional data) is limited for making conclusions about the causal association between fluoride and attention-related outcomes. Exposure misclassification may have occurred for some participants due to changes in a city's water fluoridation status over the youth's lifetime. Tap water samples were collected between 2012 and 2013 when approximately 37.4% of Canadians had access to fluoridated water as compared with 42.6% in 2007 (Public Health Agency of Canada, 2017). Thus, water fluoride measures obtained at the time of CHMS data collection may not be consistent with water fluoride levels that were antecedent to the outcomes in our study. Because the CHMS only measured postnatal fluoride exposure, we were not able to distinguish the effects of fluoride exposure during different developmental periods (e.g., prenatal versus postnatal). Recent studies have identified

pregnancy as a critical period during which fluoride exposure is linked to lowered IQ (Bashash et al., 2017; Green et al., 2019) and attention-related behaviours (Bashash et al., 2018) in offspring. Third, the method used by CHMS may not completely capture true ADHD prevalence. Because of the way that the CHMS items were phrased, the Cycle 2 sample may identify youth with a comorbid learning disability and ADHD, but not those who have ADHD and no learning disability. Nonetheless, the prevalence of ADHD in the current study (7.3%) is similar to the prevalence rate found in other studies. A meta-analysis including 175 studies from across the world obtained an overall ADHD prevalence rate of 7.2% (Thomas et al., 2015). In a 2012 sample of Canadian youth under age 24, the prevalence of ADHD was 5.4% (Hauck et al., 2017). Relatedly, the number of youth with ADHD in our study was relatively small, ranging from approximately 45 to 140 depending on the sample used for a given analysis, which limited statistical power and precision. Finally, the SDQ relies on youth or parent perceptions of symptoms. Future studies would benefit from prospective designs and more rigorous symptom assessment, particularly a structured diagnostic interview that assesses DSM-5 criteria for ADHD.

In conclusion, we found that higher tap water fluoride levels and fluoridation of municipal water supplies were associated with a higher risk of an ADHD diagnosis as well as increased symptoms of hyperactivity and inattention, especially among adolescents. These findings, which point to a potential cumulative effect of fluoride exposure, highlight the need for further investigation of the potential for fluoride-mediated developmental neurotoxicity in populations with water fluoridation.

Declaration of Competing Interest

None.

Acknowledgements

The authors would like to thank the participants of the CHMS cycles 2 and 3, as well as staff at the York, University of Toronto, and University of Manitoba Research Data Centres (RDC). We would also like to thank Dr. Debra Pepler and Ms. Rivka Green for their comments on this manuscript.

Funding

This study was funded by a Minor Research Grant from the Faculty of Health at York University awarded to C. Till. This research did not receive any funding from commercial or not-for-profit sectors.

Association Between Maternal Fluoride Exposure During Pregnancy and IQ Scores in Offspring in Canada

Rivka Green, MA; Bruce Lanphear, MD; Richard Hornung, PhD; David Flora, PhD; E. Angeles Martinez-Mier, DDS; Rachel Neufeld, BA; Pierre Ayotte, PhD; Gina Muckle, PhD; Christine Till, PhD

IMPORTANCE The potential neurotoxicity associated with exposure to fluoride, which has generated controversy about community water fluoridation, remains unclear.

OBJECTIVE To examine the association between fluoride exposure during pregnancy and IQ scores in a prospective birth cohort.

DESIGN, SETTING, AND PARTICIPANTS This prospective, multicenter birth cohort study used information from the Maternal-Infant Research on Environmental Chemicals cohort. Children were born between 2008 and 2012; 41% lived in communities supplied with fluoridated municipal water. The study sample included 601 mother-child pairs recruited from 6 major cities in Canada; children were between ages 3 and 4 years at testing. Data were analyzed between March 2017 and January 2019.

EXPOSURES Maternal urinary fluoride (MUF_{SG}), adjusted for specific gravity and averaged across 3 trimesters available for 512 pregnant women, as well as self-reported maternal daily fluoride intake from water and beverage consumption available for 400 pregnant women.

MAIN OUTCOMES AND MEASURES Children's IQ was assessed at ages 3 to 4 years using the Wechsler Primary and Preschool Scale of Intelligence-III. Multiple linear regression analyses were used to examine covariate-adjusted associations between each fluoride exposure measure and IQ score.

RESULTS Of 512 mother-child pairs, the mean (SD) age for enrollment for mothers was 32.3 (5.1) years, 463 (90%) were white, and 264 children (52%) were female. Data on MUF_{SG} concentrations, IQ scores, and complete covariates were available for 512 mother-child pairs; data on maternal fluoride intake and children's IQ were available for 400 of 601 mother-child pairs. Women living in areas with fluoridated tap water ($n = 141$) compared with nonfluoridated water ($n = 228$) had significantly higher mean (SD) MUF_{SG} concentrations (0.69 [0.42] mg/L vs 0.40 [0.27] mg/L; $P = .001$; to convert to millimoles per liter, multiply by 0.05263) and fluoride intake levels (0.93 [0.43] vs 0.30 [0.26] mg of fluoride per day; $P = .001$). Children had mean (SD) Full Scale IQ scores of 107.16 (13.26), range 52-143, with girls showing significantly higher mean (SD) scores than boys: 109.56 (11.96) vs 104.61 (14.09); $P = .001$. There was a significant interaction ($P = .02$) between child sex and MUF_{SG} (6.89; 95% CI, 0.96-12.82) indicating a differential association between boys and girls. A 1-mg/L increase in MUF_{SG} was associated with a 4.49-point lower IQ score (95% CI, -8.38 to -0.60) in boys, but there was no statistically significant association with IQ scores in girls ($B = 2.40$; 95% CI, -2.53 to 7.33). A 1-mg higher daily intake of fluoride among pregnant women was associated with a 3.66 lower IQ score (95% CI, -7.16 to -0.14) in boys and girls.

CONCLUSIONS AND RELEVANCE In this study, maternal exposure to higher levels of fluoride during pregnancy was associated with lower IQ scores in children aged 3 to 4 years. These findings indicate the possible need to reduce fluoride intake during pregnancy.

For decades, community water fluoridation has been used to prevent tooth decay. Water fluoridation is supplied to about 66% of US residents, 38% of Canadian residents, and 3% of European residents.¹ In fluoridated communities, fluoride from water and beverages made with tap water makes up 60% to 80% of daily fluoride intake in adolescents and adults.²

Fluoride crosses the placenta,³ and laboratory studies show that it accumulates in brain regions involved in learning and memory⁴ and alters proteins and neurotransmitters in the central nervous system.⁵ Higher fluoride exposure from drinking water has been associated with lower children's intelligence in a meta-analysis⁶ of 27 epidemiologic studies and in studies^{7,8} including biomarkers of fluoride exposure. However, most prior studies were cross-sectional and conducted in regions with higher water fluoride concentrations (0.88–31.6 mg/L; to convert to millimoles per liter, multiply by 0.05263) than levels considered optimal (ie, 0.7 mg/L) in North America.⁹ Further, most studies did not measure exposure during fetal brain development. In a longitudinal birth cohort study involving 299 mother-child pairs in Mexico City, Mexico, a 1-mg/L increase in maternal urinary fluoride (MUF) concentration was associated with a 6-point (95% CI, –10.84 to –1.74) lower IQ score among school-aged children.¹⁰ In this same cohort, MUF was also associated with more attention-deficit/hyperactivity disorder-like symptoms.¹¹ Urinary fluoride concentrations among pregnant women living in fluoridated communities in Canada are similar to concentrations among pregnant women living in Mexico City.¹² However, it is unclear whether fluoride exposure during pregnancy is associated with cognitive deficits in a population receiving optimally fluoridated water.

This study examined whether exposure to fluoride during pregnancy was associated with IQ scores in children in a Canadian birth cohort in which 40% of the sample was supplied with fluoridated municipal water.

Methods

Study Cohort

Between 2008 and 2011, the Maternal-Infant Research on Environmental Chemicals (MIREC) program recruited 2001 pregnant women from 10 cities across Canada. Women who could communicate in English or French, were older than 18 years, and were within the first 14 weeks of pregnancy were recruited from prenatal clinics. Participants were not recruited if there was a known fetal abnormality, if they had any medical complications, or if there was illicit drug use during pregnancy. Additional details are in the cohort profile description.¹³

A subset of 610 children in the MIREC Study was evaluated for the developmental phase of the study at ages 3 to 4 years; these children were recruited from 6 of 10 cities included in the original cohort: Vancouver, Montreal, Kingston, Toronto, Hamilton, and Halifax. Owing to budgetary restraints, recruitment was restricted to the 6 cities with the most participants who fell into the age range required for

Key Points

Question Is maternal fluoride exposure during pregnancy associated with childhood IQ in a Canadian cohort receiving optimally fluoridated water?

Findings In this prospective birth cohort study, fluoride exposure during pregnancy was associated with lower IQ scores in children aged 3 to 4 years.

Meaning Fluoride exposure during pregnancy may be associated with adverse effects on child intellectual development, indicating the possible need to reduce fluoride intake during pregnancy.

the testing during the data collection period. Of the 610 children, 601 (98.5%) completed neurodevelopmental testing; 254 (42.3%) of these children lived in nonfluoridated regions and 180 (30%) lived in fluoridated regions; for 167 (27.7%) fluoridation status was unknown owing to missing water data or reported not drinking tap water (Figure 1).

This study was approved by the research ethics boards at Health Canada, York University, and Indiana University. All women signed informed consent forms for both mothers and children.

Maternal Urinary Fluoride Concentration

We used the mean concentrations of MUF measured in urine spot samples collected across each trimester of pregnancy at a mean (SD) of 11.57 (1.57), 19.11 (2.39), and 33.11 (1.50) weeks of gestation. Owing to the variability of urinary fluoride measurement and fluoride absorption during pregnancy,¹⁴ we only included women who had all 3 urine samples. In our previous work, these samples were moderately correlated; intraclass correlation coefficient (ICC) ranged from 0.37 to 0.40.¹²

Urinary fluoride concentration was analyzed at the Indiana University School of Dentistry using a modification of the hexamethyldisiloxane (Sigma Chemical Co) microdiffusion procedure¹⁵ and described in our previous work.¹² Fluoride concentration could be measured to 0.02 mg/L. We excluded 2 samples (0.002%) because the readings exceeded the highest concentration standard (5 mg/L) and there was less certainty of these being representative exposure values.

To account for variations in urine dilution at the time of measurement, we adjusted MUF concentrations for specific gravity (SG) using the following equation: $MUF_{SG} = MUF_i \times (SG_M - 1) / (SG_i - 1)$, where MUF_{SG} is the SG-adjusted fluoride concentration (in milligrams of fluoride per liter), MUF_i is the observed fluoride concentration, SG_i is the SG of the individual urine sample, and SG_M is the median SG for the cohort.¹⁶ For comparison, we also adjusted MUF using the same creatinine adjustment method that was used in the 2017 Mexican cohort.¹⁰

Water Fluoride Concentration

Water treatment plants measured fluoride levels daily if fluoride was added to municipal drinking water and weekly or monthly if fluoride was not added to water.¹² We matched

Figure 1. Flowchart of Inclusion Criteria

participants' postal codes with water treatment plant zones, allowing an estimation of water fluoride concentration for each woman by averaging water fluoride concentrations (in milligrams per liter) during the duration of pregnancy. We only included women who reported drinking tap water during pregnancy.

Daily Fluoride Intake in Mothers

We obtained information on consumption of tap water and other water-based beverages (tea and coffee) from a self-report questionnaire completed by mothers during the first and third trimesters. This questionnaire was used in the original MREC cohort and has not been validated. Also, for this study, we developed methods to estimate and calculate fluoride intake that have not yet been validated. To estimate fluoride intake from tap water consumed per day (milligrams per day), we multiplied each woman's consumption of water and beverages by her water fluoride concentration (averaged across pregnancy) and multiplied by 0.2 (fluoride content for a 200-mL cup). Because black tea contains a high fluoride content (2.6 mg/L),^{17,18} we also estimated the amount of fluoride consumed from black tea by multiplying each cup of black tea by 0.52 mg (mean fluoride content in a 200-mL cup of black tea made with deionized water) and added this to the fluoride intake variable. Green tea also contains varying levels of fluoride; therefore, we used the mean for the green teas listed by the US Department of Agriculture (1.935 mg/L).¹⁸ We multiplied each cup of green tea by 0.387 mg (fluoride content in a 200-mL cup of green tea made with deionized water) and added this to the fluoride intake variable.

Primary Outcomes

We assessed children's intellectual abilities with the Wechsler Preschool and Primary Scale of Intelligence, Third Edition. Full Scale IQ (FSIQ), a measure of global intellectual functioning, was the primary outcome. We also assessed verbal IQ (VIQ), representing verbal reasoning and comprehension, and performance IQ (PIQ), representing nonverbal reasoning, spatial processing, and visual-motor skills.

Covariates

We selected covariates from a set of established factors associated with fluoride metabolism (eg, time of void and time since last void) and children's intellectual abilities (eg, child sex, maternal age, gestational age, and parity) (Table 1). Mother's race/ethnicity was coded as white or other, and maternal education was coded as either bachelor's degree or higher or trade school diploma or lower. The quality of a child's home environment was measured by the Home Observation for Measurement of the Environment (HOME)-Revised Edition¹⁹ on a continuous scale. We also controlled for city and, in some models, included self-reported exposure to secondhand smoke (yes/no) as a covariate.

Statistical Analyses

In our primary analysis, we used linear regression analyses to estimate the associations between our 2 measures of fluoride exposure (MUF_{SG} and fluoride intake) and children's FSIQ scores. In addition to providing the coefficient corresponding to a 1-mg difference in fluoride exposure, we also estimated coefficients corresponding to a fluoride exposure

Abbreviations: BMI, body mass index (calculated as weight in kilograms divided by height in meters squared); CAD, Canadian dollars; FSIQ, Full Scale IQ; HOME, Home Observation for Measurement of the Environment; MUF_{SG}, maternal urinary fluoride adjusted for specific gravity.

SI conversion factor: To convert fluoride to millimoles per liter, multiply by 0.05263.

^a Owing to missing water treatment plant data and/or MUF data, the samples are distinct with some overlapping participants in both groups (n = 369).

^b All of the listed variables were tested as potential covariates, as well as the following: paternal variables (age, education, employment status, smoking status, and race/ethnicity); maternal chronic condition during pregnancy and birth country; breastfeeding duration; and time of void and time since last void.

^c Maternal urinary fluoride (averaged across all 3 trimesters) and corrected for specific gravity.

^d The FSIQ score has a mean (SD) of 100 (15); US population norms used.

^e Owing to missing water treatment plant data, the samples in the fluoridated and nonfluoridated regions do not add up to the MUF sample size.

difference spanning the 25th to 75th percentile range (which corresponds to a 0.33 mg/L and 0.62 mg F/d difference in MUF_{SG} and fluoride intake, respectively) as well as the 10th to 90th percentile range (which corresponds to a 0.70 mg/L and 1.04 mg F/d difference in MUF_{SG} and fluoride intake, respectively).

We retained a covariate in the model if its *P* value was less than .20 or its inclusion changed the regression coefficient of the variable associated factor by more than 10% in any of the IQ models. Regression diagnostics confirmed that there were no collinearity issues in any of the IQ models

with MUF_{SG} or fluoride intake (variance inflation factor <2 for all covariates). Residuals from each model had approximately normal distributions, and their Q-Q plots revealed no extreme outliers. Plots of residuals against fitted values did not suggest any assumption violations and there were no substantial influential observations as measured by Cook distance. Including quadratic or natural-log effects of MUF_{SG} or fluoride intake did not significantly improve the regression models. Thus, we present the more easily interpreted estimates from linear regression models. Additionally, we examined separate models with 2 linear splines to test

whether the MUF_{SG} association significantly differed between lower and higher levels of MUF_{SG} based on 3 knots, which were set at 0.5 mg/L (mean MUF_{SG}), 0.8 mg/L (threshold seen in the Mexican birth cohort),¹⁰ and 1 mg/L (optimal concentration in the United States until 2015).²⁰ For fluoride intake, knots were set at 0.4 mg (mean fluoride intake), 0.8 mg, and 1 mg (in accordance with MUF_{SG}). We also examined sex-specific associations in all models by testing the interactions between child sex and each fluoride measure.

In sensitivity analyses, we tested whether the associations between MUF_{SG} and IQ were confounded by maternal blood concentrations of lead,²¹ mercury,²¹ manganese,^{21,22} perfluoro-octanoic acid,²³ or urinary arsenic.²⁴ We also conducted sensitivity analyses by removing IQ scores that were greater than or less than 2.5 standard deviations from the sample mean. Additionally, we examined whether using MUF adjusted for creatinine instead of SG affected the results.

In additional analyses, we examined the association between our 2 measures of fluoride exposure (MUF_{SG} and fluoride intake) with VIQ and PIQ. Additionally, we examined whether water fluoride concentration was associated with FSIQ, VIQ, and PIQ scores.

For all analyses, statistical significance tests with a type I error rate of 5% were used to test sex interactions, while 95% confidence intervals were used to estimate uncertainty. Analyses were conducted using R software (the R Foundation).²⁵ The *P* value level of significance was .05, and all tests were 2-sided.

Results

For the first measure of fluoride exposure, MUF_{SG} , 512 of 601 mother-child pairs (85.2%) who completed the neurodevelopmental visit had urinary fluoride levels measured at each trimester of the mother's pregnancy and complete covariate data (Figure 1); 89 (14.8%) were excluded for missing MUF_{SG} at 1 or more trimesters (*n* = 75) or missing 1 or more covariates included in the regression (*n* = 14) (Figure 1). Of the 512 mother-child pairs with MUF_{SG} data (and all covariates), 264 children were female (52%).

For the second measure of fluoride exposure, fluoride intake from maternal questionnaire, data were available for 400 of the original 601 mother-child pairs (66.6%): 201 women (33.4%) were excluded for reporting not drinking tap water (*n* = 59), living outside of the predefined water treatment plant zone (*n* = 108), missing beverage consumption data (*n* = 20), or missing covariate data (*n* = 14) (Figure 1).

Children had mean FSIQ scores in the average range (population normed) (mean [SD], 107.16 [13.26], range = 52-143), with girls (109.56 [11.96]) showing significantly higher scores than boys (104.61 [14.09]; *P* < .001) (Table 1). The demographic characteristics of the 512 mother-child pairs included in the primary analysis were not substantially different from the original MIREC cohort or subset of mother-child pairs without 3 urine samples (eTable 1 in the Supplement). Of the 400 mother-child pairs with fluoride intake data (and all covariates), 118 of

Figure 2. Distribution of Fluoride Levels in Maternal Urine and for Estimated Fluoride Intake by Fluoridation Status

To convert fluoride to millimoles per liter, multiply by 0.05263.

238 (50%) in the group living in a nonfluoridated region were female and 83 of 162 (51%) in the group living in a fluoridated region were female.

Fluoride Measurements

The median MUF_{SG} concentration was 0.41 mg/L (range, 0.06-2.44 mg/L). Mean MUF_{SG} concentration was significantly higher among women (*n* = 141) who lived in communities with fluoridated drinking water (0.69 [0.42] mg/L) compared with women (*n* = 228) who lived in communities without fluoridated drinking water (0.40 [0.27] mg/L; *P* < .001) (Table 1; Figure 2).

The median estimated fluoride intake was 0.39 mg per day (range, 0.01-2.65 mg). As expected, the mean (SD) fluoride intake was significantly higher for women (162 [40.5%]) who lived in communities with fluoridated drinking water (mean [SD], 0.93 [0.43] mg) than women (238 [59.5%]) who lived in communities without fluoridated drinking water (0.30 [0.26] mg; *P* < .001) (Table 1; Figure 2). The MUF_{SG} was moderately correlated with fluoride intake (*r* = 0.49; *P* < .001) and water fluoride concentration (*r* = 0.37; *P* < .001).

Maternal Urinary Fluoride Concentrations and IQ

Before covariate adjustment, a significant interaction (*P* for interaction = .03) between MUF_{SG} and child sex (*B* = 7.24; 95% CI, 0.81-13.67) indicated that MUF_{SG} was associated with FSIQ in boys; an increase of 1 mg/L MUF_{SG} was associated with a 5.01 (95% CI, -9.06 to -0.97; *P* = .02) lower FSIQ score in boys. In contrast, MUF_{SG} was not significantly associated with FSIQ score in girls (*B* = 2.23; 95% CI, -2.77 to 7.23; *P* = .38) (Table 2).

Adjusting for covariates, a significant interaction (*P* for interaction = .02) between child sex and MUF_{SG} (*B* = 6.89; 95% CI, 0.96-12.82) indicated that an increase of 1 mg/L of MUF_{SG} was associated with a 4.49 (95% CI, -8.38 to -0.60; *P* = .02) lower FSIQ score for boys. An increase from the 10th to 90th percentile of MUF_{SG} was associated with a 3.14 IQ decrement among boys (Table 2; Figure 3). In contrast, MUF_{SG} was not significantly associated with FSIQ score in girls (*B* = 2.43; 95% CI, -2.51 to 7.36; *P* = .33).

Table 2. Unadjusted and Adjusted Associations Estimated From Linear Regression Models of Fluoride Exposure Variables and FSIQ Scores

Variable	Difference (95% CI)			
	Unadjusted	Adjusted Estimates, Regression Coefficients Indicate Change in Outcome per ^a		
MUF _{SG} ^{b,c}	-2.60 (-5.80 to 0.60)	1 mg	25th to 75th Percentiles	10th to 90th Percentiles
Boys	-5.01 (-9.06 to -0.97)	-4.49 (-8.38 to -0.60)	-1.48 (-2.76 to -0.19)	-3.14 (-5.86 to -0.42)
Girls	2.23 (-2.77 to 7.23)	2.40 (-2.53 to 7.33)	0.79 (-0.83 to 2.42)	1.68 (-1.77 to 5.13)
Fluoride intake ^{d,e}	-3.19 (-5.94 to -0.44)	-3.66 (-7.16 to -0.15)	-2.26 (-4.45 to -0.09)	-3.80 (-7.46 to -0.16)

Abbreviations: FSIQ, Full Scale IQ; HOME, Home Observation for Measurement of the Environment; MUF_{SG}, maternal urinary fluoride adjusted for specific gravity.

^a Adjusted estimates pertain to predicted FSIQ difference for a value spanning the interquartile range (25th to 75th percentiles) and 80th central range (10th to 90th percentiles): (1) MUF_{SG}: 0.33 mg/L, 0.70 mg/L, respectively; (2) fluoride intake: 0.62 mg, 1.04 mg, respectively.

^b n = 512.

^c Adjusted for city, HOME score, maternal education, race/ethnicity, and including child sex interaction.

^d n = 400.

^e Adjusted for city, HOME score, maternal education, race/ethnicity, child sex, and prenatal secondhand smoke exposure.

Figure 3. Covariate Results of Multiple Linear Regression Models of Full Scale IQ (FSIQ) from Maternal Urinary Fluoride Concentration by Child Sex (n = 512) and Total Fluoride Intake Estimated from Daily Maternal Beverage Consumption (n = 400)

B, Community fluoridation status (CWF) is shown for each woman; black dots represent women living in nonfluoridated (non-FL) communities and blue dots represent women living in fluoridated (FL) communities.

Estimated Fluoride Intake and IQ

A 1-mg increase in fluoride intake was associated with a 3.66 (95% CI, -7.16 to -0.15; $P = .04$) lower FSIQ score among boys and girls (Table 2; Figure 3). The interaction between child sex and fluoride intake was not statistically significant ($B = 1.17$; 95% CI, -4.08 to 6.41; P for interaction = .66).

Sensitivity Analyses

Adjusting for lead, mercury, manganese, perfluorooctanoic acid, or arsenic concentrations did not substantially change the overall estimates of MUF_{SG} for boys or girls (eTable 2 in the Supplement). Use of MUF adjusted for creatinine did not substantially alter the associations with FSIQ (eTable 2 in the Supplement). Including time of void and time since last void did not substantially change the regression coefficient of MUF_{SG} among boys or girls.

Estimates for determining the association between MUF_{SG} and PIQ showed a similar pattern with a statistically significant interaction between MUF_{SG} and child sex (P for interaction = .007). An increase of 1 mg/L MUF_{SG} was associated with a 4.63 (95% CI, -9.01 to -0.25; $P = .04$) lower PIQ score in boys, but the association was not statistically significant in girls

($B = 4.51$; 95% CI, -1.02 to 10.05; $P = .11$). An increase of 1 mg/L MUF_{SG} was not significantly associated with VIQ in boys ($B = -2.85$; 95% CI, -6.65 to 0.95; $P = .14$) or girls ($B = 0.55$; 95% CI, -4.28 to 5.37; $P = .82$); the interaction between MUF_{SG} and child sex was not statistically significant (P for interaction = .25) (eTable 3 in the Supplement).

Consistent with the findings on estimated maternal fluoride intake, increased water fluoride concentration (per 1 mg/L) was associated with a 5.29 (95% CI, -10.39 to -0.19) lower FSIQ score among boys and girls and a 13.79 (95% CI, -18.82 to -7.28) lower PIQ score (eTable 4 in the Supplement).

Discussion

Using a prospective Canadian birth cohort, we found that estimated maternal exposure to higher fluoride levels during pregnancy was associated with lower IQ scores in children. This association was supported by converging findings from 2 measures of fluoride exposure during pregnancy. A difference in MUF_{SG} spanning the interquartile range for the entire sample (ie, 0.33 mg/L), which is roughly the difference in

MUF_{SG} concentration for pregnant women living in a fluoridated vs a nonfluoridated community, was associated with a 1.5-point IQ decrement among boys. An increment of 0.70 mg/L in MUF_{SG} concentration was associated with a 3-point IQ decrement in boys; about half of the women living in a fluoridated community have a MUF_{SG} equal to or greater than 0.70 mg/L. These results did not change appreciably after controlling for other key exposures such as lead, arsenic, and mercury.

To our knowledge, this study is the first to estimate fluoride exposure in a large birth cohort receiving optimally fluoridated water. These findings are consistent with that of a Mexican birth cohort study that reported a 6.3 decrement in IQ in preschool-aged children compared with a 4.5 decrement for boys in our study for every 1 mg/L of MUF.¹⁰ The findings of the current study are also concordant with ecologic studies that have shown an association between higher levels of fluoride exposure and lower intellectual abilities in children.^{7,8,26} Collectively, these findings support that fluoride exposure during pregnancy may be associated with neurocognitive deficits.

In contrast with the Mexican study,¹⁰ the association between higher MUF_{SG} concentrations and lower IQ scores was observed only in boys but not in girls. Studies of fetal and early childhood fluoride exposure and IQ have rarely examined differences by sex; of those that did, some reported no differences by sex.^{10,27-29} Most rat studies have focused on fluoride exposure in male rats,³⁰ although 1 study³¹ showed that male rats were more sensitive to neurocognitive effects of fetal exposure to fluoride. Testing whether boys are potentially more vulnerable to neurocognitive effects associated with fluoride exposure requires further investigation, especially considering that boys have a higher prevalence of neurodevelopmental disorders such as ADHD, learning disabilities, and intellectual disabilities.³² Adverse effects of early exposure to fluoride may manifest differently for girls and boys, as shown with other neurotoxicants.³³⁻³⁶

The estimate of maternal fluoride intake during pregnancy in this study showed that an increase of 1 mg of fluoride was associated with a decrease of 3.7 IQ points across boys and girls. The finding observed for fluoride intake in both boys and girls may reflect postnatal exposure to fluoride, whereas MUF primarily captures prenatal exposure. Importantly, we excluded women who reported that they did not drink tap water and matched water fluoride measurements to time of pregnancy when estimating maternal fluoride intake. None of the fluoride concentrations measured in municipal drinking water were greater than the maximum acceptable concentration of 1.5 mg/L set by Health Canada; most (94.3%) were lower than the 0.7 mg/L level considered optimal.³⁷

Water fluoridation was introduced in the 1950s to prevent dental caries before the widespread use of fluoridated dental products. Originally, the US Public Health Service set the optimal fluoride concentrations in water from 0.7 to 1.2 mg/L to achieve the maximum reduction in tooth decay and minimize the risk of enamel fluorosis.³⁸ Fluorosis, or mottling, is a symptom of excess fluoride intake from any source occurring during the period of tooth development. In

2012, 68% of adolescents had very mild to severe enamel fluorosis.³⁹ The higher prevalence of enamel fluorosis, especially in fluoridated areas,⁴⁰ triggered renewed concern about excessive ingestion of fluoride. In 2015, in response to fluoride overexposure and rising rates of enamel fluorosis,^{39,41,42} the US Public Health Service recommended an optimal fluoride concentration of 0.7 mg/L, in line with the recommended level of fluoride added to drinking water in Canada to prevent caries. However, the beneficial effects of fluoride predominantly occur at the tooth surface after the teeth have erupted.⁴³ Therefore, there is no benefit of systemic exposure to fluoride during pregnancy for the prevention of caries in offspring.⁴⁴ The evidence showing an association between fluoride exposure and lower IQ scores raises a possible new concern about cumulative exposures to fluoride during pregnancy, even among pregnant women exposed to optimally fluoridated water.

Strengths and Limitations

Our study has several strengths and limitations. First, urinary fluoride has a short half-life (approximately 5 hours) and depends on behaviors that were not controlled in our study, such as consumption of fluoride-free bottled water or swallowing toothpaste prior to urine sampling. We minimized this limitation by using 3 serial urine samples and tested for time of urine sample collection and time since last void, but these variables did not alter our results. Second, although higher maternal ingestion of fluoride corresponds to higher fetal plasma fluoride levels,⁴⁵ even serial maternal urinary spot samples may not precisely represent fetal exposure throughout pregnancy. Third, while our analyses controlled for a comprehensive set of covariates, we did not have maternal IQ data. However, there is no evidence suggesting that fluoride exposure differs as a function of maternal IQ; our prior study did not observe a significant association between MUF levels and maternal education level.¹² Moreover, a greater proportion of women living in fluoridated communities (124 [76%]) had a university-level degree compared with women living in nonfluoridated communities (158 [66%]). Nonetheless, despite our comprehensive array of covariates included, this observational study design could not address the possibility of other unmeasured residual confounding. Fourth, fluoride intake did not measure actual fluoride concentration in tap water in the participant's home; Toronto, for example, has overlapping water treatment plants servicing the same household. Similarly, our fluoride intake estimate only considered fluoride from beverages; it did not include fluoride from other sources such as dental products or food. Furthermore, fluoride intake data were limited by self-report of mothers' recall of beverage consumption per day, which was sampled at 2 points of pregnancy, and we lacked information regarding specific tea brand.^{17,18} In addition, our methods of estimating maternal fluoride intake have not been validated; however, we show construct validity with MUF. Fifth, this study did not include assessment of postnatal fluoride exposure or consumption. However, our future analyses will assess exposure to fluoride in the MIREC cohort in infancy and early childhood.

Conclusions

In this prospective birth cohort study from 6 cities in Canada, higher levels of fluoride exposure during preg-

nancy were associated with lower IQ scores in children measured at age 3 to 4 years. These findings were observed at fluoride levels typically found in white North American women. This indicates the possible need to reduce fluoride intake during pregnancy.

Water fluoridation

Intellectual function

ABSTRACT

Background: Infant consumption of formula reconstituted with fluoridated water can lead to excessive fluoride intake. We examined the association between fluoride exposure in infancy and intellectual ability in children who lived in fluoridated or non-fluoridated cities in Canada.

Methods: We examined 398 mother-child dyads in the Maternal-Infant Research on Environmental Chemicals cohort who reported drinking tap water. We estimated water fluoride concentration using municipal water reports. We used linear regression to analyze the association between fluoride exposure and IQ scores, measured by the Wechsler Primary and Preschool Scale of Intelligence-III at 3–4 years. We examined whether feeding status (breast-fed versus formula-fed) modified the impact of water fluoride and if fluoride exposure during fetal development attenuated this effect. A second model estimated the association between fluoride intake from formula and child IQ.

Results: Thirty-eight percent of mother-child dyads lived in fluoridated communities. An increase of 0.5 mg/L in water fluoride concentration (approximately equaling the difference between fluoridated and non-fluoridated regions) corresponded to a 9.3- and 6.2-point decrement in Performance IQ among formula-fed (95% CI: −13.77, −4.76) and breast-fed children (95% CI: −10.45, −1.94). The association between water fluoride concentration and Performance IQ remained significant after controlling for fetal fluoride exposure among formula-fed ($B = -7.93$, 95% CI: −12.84, −3.01) and breastfed children ($B = -6.30$, 95% CI: −10.92, −1.68). A 0.5 mg increase in fluoride intake from infant formula corresponded to an 8.8-point decrement in Performance IQ (95% CI: −14.18, −3.34) and this association remained significant after controlling for fetal fluoride exposure ($B = -7.62$, 95% CI: −13.64, −1.60).

Conclusions: Exposure to increasing levels of fluoride in tap water was associated with diminished non-verbal intellectual abilities; the effect was more pronounced among formula-fed children.

1. Introduction

Fluoride can occur naturally in water and, in some communities, is added to water supplies to reach the recommended concentration of 0.7 mg/L for the prevention of tooth decay (Health Canada, 2010).

About 74% of Americans and 38% of Canadians on municipal water are supplied with fluoridated drinking water. Water fluoridation has been reported to reduce the prevalence of tooth decay by 26% to 44% (Iheozor-Ejiofor et al., 2015; National Health and Medical Research Council (NHMRC), 2017) in youth and by 26% (Iheozor-Ejiofor et al.,

Abbreviations: BF, breastfed; FF, formula fed; CI, confidence intervals; HOME, home observation for measurement of the environment; IQ, intelligence quotient; FSIQ, full scale IQ; PIQ, performance IQ; VIQ, verbal IQ; MIREC, maternal-infant research on environmental chemicals; MUF, maternal urinary fluoride; SD, standard deviation

2015) to 27% (NHMRC, 2017) in adults. Infants who are fed formula reconstituted with fluoridated water have approximately three to four times greater exposure to fluoride than adults (National Research Council (NRC), 2006) on a per body-weight basis. Formula-fed infants residing in fluoridated areas have an approximate 70-fold higher fluoride intake than exclusively breastfed infants (Ekstrand, 1981; Zohoori et al., 2018; United States Environmental Protection Agency, 2010).

The prevalence of enamel fluorosis, a discoloration of enamel resulting from chronic, excessive ingestion of fluoride during tooth development (Brothwell and Limeback, 2003; Buzalaf et al., 2001), is higher among formula-fed infants than breastfed infants (Buzalaf et al., 2001; Do et al., 2012; Fv et al., 2012; Hong et al., 2006; Walton and Messer, 1981). While enamel fluorosis develops from excess fluoride exposure during the first four years of life, (Levy et al., 2010) the first 12 months are the most vulnerable period (Hong et al., 2006). The risk of fluorosis increases with higher levels of fluoride in the water supply for formula-fed infants (Hujoel et al., 2009).

Breastmilk contains extremely low concentrations of fluoride (0.005–0.01 mg/L) due to the limited transfer of fluoride in plasma into breastmilk (Dabeka et al., 1986; Ekstrand, 1981; Ekstrand and Hardell, 1984; Esala et al., 1982; Faraji et al., 2014; Zohoori et al., 2018). Exclusive breastfeeding for six months, which is recommended by current practice guidelines (Critch, 2013; Eidelman, 2012), is reported by 25% of mothers in the United States (Breastfeeding Report Card, United States, 2018) and Canada (Health Canada, 2001). Ninety percent of bottle-fed infants are fed powdered formula (Infant Feeding Practices Survey II) and 75% of mothers report using tap water to reconstitute formula (Van Winkle et al., 1995). Thus, reconstituted formula is the major source of nutrition for many infants in the United States and Canada.

Despite growing concerns about excessive exposure to fluoride during infancy and the vulnerability of the developing brain (Rice and Barone, 2000; Grandjean and Landrigan, 2006), no studies have tested the potential neurotoxicity of using optimally fluoridated drinking water to reconstitute formula during infancy (Harriehausen et al., 2019). Increased fluoride exposure during fetal brain development was associated with diminished IQ scores in two birth cohort studies (Bashash et al., 2017; Green et al., 2019; Valdez Jiménez et al., 2017), among a number of recent studies conducted in endemic fluorosis areas (Karimzade et al., 2014; Dong et al., 2018; Zhang et al., 2015), as well as a 2012 meta-analysis of 27 ecologic studies (Choi et al., 2012). Increased fluoride exposure has also been linked with ADHD-related behaviors in children (Malin and Till, 2015; Bashash et al., 2018; Riddell et al., 2019).

We investigated the association between water fluoride concentration and intellectual abilities of Canadian children who were formula-fed or breastfed. In addition, we tested whether postnatal effects of fluoride exposure on child IQ remained after controlling for fetal exposure.

2. Materials and methods

2.1. Study population

Between 2008 and 2011, the Maternal-Infant Research on Environmental Chemicals (MIREC) program recruited 2001 pregnant women from ten Canadian cities to participate in a longitudinal pregnancy cohort study. Women who could communicate in English or French, were > 17 years, and were < 14 weeks gestation were recruited from prenatal clinics. Participants were excluded if there was a known fetal abnormality, if they had any medical complications, or if there was known illicit drug use during pregnancy. Additional details are in the cohort profile description (Arbuckle et al., 2013).

Of the 610 children who were recruited to participate in the developmental follow-up phase of the study (MIREC-Child Development

Plus), 601 completed all testing. Children were recruited from six of the cities in the original cohort (Vancouver, Toronto, Hamilton, Halifax, Kingston, Montreal); approximately half of the children lived in non-fluoridated cities and half lived in fluoridated cities.

This study received ethics approval from Health Canada and York University.

2.2. Infant feeding assessment

When children were between 30 and 48 months of age, mothers completed an infant feeding questionnaire asking, “How old was your baby when you ceased breastfeeding exclusively? At what age did you introduce other type of milk or food to your baby?”. Women who breastfed exclusively for six months or longer were included in the breastfeeding (BF) group; those who reported introducing formula within the first six months (never breastfed or partial breastfeeding) were included in the formula-feeding (FF) group.

To explore the possibility of recall or response bias of mothers completing the questionnaire, we compared information reported by mothers when their children were between 30 and 48 months of age (i.e. time when the questionnaire was completed for classifying the BF and FF groups) with information reported by a subset of women at an earlier visit when their children were between 6 and 8 months of age. Information about infant feeding was only available for 11% of the sample at the infant visit (note that responses could only be matched for women who had stopped breastfeeding at the time the questionnaire was completed at the infant visit). Among women who provided information at both occasions, the median difference for when breastfeeding was reported to be ceased was 0 months; responses were within 1.5 months of each other for two-thirds of this subsample.

We dichotomized feeding status at six months because the Canadian Pediatric Society and American Academy of Pediatrics both recommend exclusive breastfeeding for six months (Critch, 2013; Eidelman, 2012). Moreover, formula-fed infants who are younger than six-months derive most of their nutrition from formula, placing this group at highest risk of exceeding the recommended upper limit (0.7 mg/d) for fluoride (Harriehausen et al., 2019; Institutes of Medicine, 1997; National Research Council (NRC), 2006). Finally, fluoride intake differences become less evident when other dietary sources of fluoride are introduced at around six months (Zohoori et al., 2018).

2.3. Infant fluoride exposure

We estimated fluoride concentrations in drinking water by accessing daily or monthly reports provided by water treatment plants. Water reports were first linked with mothers' postal codes and the daily or weekly amounts were averaged over the first six-months of the child's life. We only included participants whose postal codes could be linked to a water treatment plant that provided water fluoride measurements. We also excluded participants who reported that their primary drinking source was from a well or ‘other’ (e.g. bottled water) (Table S1). Further details can be found in our previous report (Till et al., 2018).

To obtain a continuous fluoride exposure estimate collapsed across the BF and FF groups, we estimated fluoride intake from formula (in mg F/day) by multiplying water fluoride concentration by the amount of time that the infant was not exclusively breastfed in the first year using the following equation:

$$\text{Fluoride intake from formula} = (\text{water_F mg/L}) * (1 - \#mo_excl_BF / 11.99) * 0.80 \text{ L/day}$$

where *water_F mg/L* refers to the average water fluoride concentration and *1-#mo_excl_BF/11.99* represents the proportion over the 12-month period the infant was not exclusively breastfed. A value near one indicates that an infant was primarily formula-fed over the 12 months whereas a value near zero indicates an infant primarily breastfed. We

estimated fluoride intake based on an average of 0.80 L of water used to reconstitute powdered formula as suggested by an infant food diary completed for infants in a prior study (Carignan et al., 2015); the average milk intake at 3 months of age is 0.812 L per day, ranging from 0.523 to 1.124 L (Dewey et al., 1991). Because we did not know the type of formula used (i.e. soy- or milk-based), we did not add fluoride derived from formula to our fluoride intake estimate. Previous studies have indicated that fluoride from water used in formula is a greater source of fluoride than fluoride found in formula (Buzalaf et al., 2004).

2.4. Fetal fluoride exposure

We used maternal urinary fluoride (MUF) adjusted for specific gravity as a proxy of fetal fluoride exposure. MUF, which was derived by averaging three spot samples collected across all three trimesters of pregnancy, was considered our most reliable measure of exposure (Till et al., 2018). Urinary fluoride concentrations were analyzed at the Indiana University School of Dentistry using a modification (Martínez-Mier et al., 2011) of the hexamethyldisiloxane (Sigma Chemical Co., USA) micro-diffusion procedure previously described (Green et al., 2019).

2.5. Intelligence assessment

We assessed children's intellectual abilities between ages 3.0 and 4.0 years with the Wechsler Preschool and Primary Scale of Intelligence-III (Wechsler, 2002) using United States population-based normative data ($mean = 100$, $SD = 15$). Outcomes included Full Scale IQ (FSIQ), a measure of global intellectual functioning, Verbal IQ (VIQ), a measure of verbal reasoning, and Performance IQ (PIQ), a measure of non-verbal reasoning and visual-motor coordination skills.

2.6. Covariates

We adjusted for potential confounding by selecting covariates *a priori* that have been associated with fluoride, breastfeeding, and children's intellectual abilities. Final covariates included child's sex and age at testing, maternal education (dichotomized as either a bachelor's degree or higher versus trade school diploma or lower), maternal race (white or not), second-hand smoke in the home (yes, no), and quality of the child's home environment (measured at time of testing using the Home Observation for Measurement of the Environment (HOME) - Revised Edition (Caldwell and Bradley, 1984). For each analysis, a covariate was retained in the final model if its p -value was < 0.20 or its inclusion changed the regression coefficient of water fluoride concentration or fluoride intake from formula by more than 10% (Kleinbaum et al., 1982). City was not included as a covariate in Model 1 because it was strongly multi-collinear with water fluoride concentration ($VIF > 20$). City was also excluded from Model 2 because fluoride intake from formula is a function of water fluoride concentration and was therefore deemed redundant.

2.7. Statistical analyses

We used linear regression to model differences in child IQ by water fluoride concentration while controlling for covariates. In our first model, we examined whether feeding status (BF or FF) modified the impact of water fluoride. In our second model, we estimated the association between fluoride intake from formula and child IQ. We controlled potential confounders by including them simultaneously with predictors.

In secondary analyses, we controlled for MUF during pregnancy in both models to account for fetal exposure. We also tested for sex-specific effects because we previously found that MUF concentration was only associated with diminished FSIQ in males (Green et al., 2019).

Regression diagnostics indicated no assumption violations

pertaining to linearity, normality, or homogeneity of variance. Specifically, QQ-plots of residuals were consistent with a normal distribution and plots of residuals against fitted values did not suggest any assumption violations. Two observations were investigated based on a plot of Cook's D that suggested they may be influential; these cases had extremely low IQ scores that were more than 2.5 standard deviations from the sample mean. In a sensitivity analyses, we re-estimated the models after removing these two observations. Finally, variance inflation factors indicated no concerns with excessive multicollinearity.

To aid interpretation, we divided all regression coefficients by 2 so that they represent the predicted IQ difference per 0.5 mg/L of fluoride in tap water or 0.5 mg fluoride from formula; 0.5 mg/L corresponds to the approximate difference between mean water fluoride level in fluoridated versus non-fluoridated regions in our sample.

3. Results

Of the 601 children who completed neurodevelopmental testing, 591 (99%) mother-child pairs completed the infant feeding questionnaire and IQ testing (BF: $n = 296$; FF: $n = 295$). Of these, 398 (67.3%) pairs reported drinking tap water, had water fluoride data and complete covariate data (BF: $n = 200$; FF: $n = 198$). The demographic characteristics of women included in the current analyses ($n = 398$) were not substantially different from the original MIREC cohort ($N = 1945$) or the subset without complete water fluoride and covariate data ($n = 203$) (Table S2, Mcknight-hanes et al., 1988).

Among the BF group, more women who lived in a fluoridated region had a bachelor's degree or higher compared with those in a non-fluoridated region (86 vs. 74%, $p = .001$) (Table 1). Compared with the FF group, women in the BF group were more educated, more likely to be married or common law, and had higher HOME scores (all $ps < 0.05$). The BF group had significantly higher FSIQ and VIQ scores relative to the FF group (Table 1; Fig. S1). Children living in a fluoridated region had a significantly lower PIQ score, but higher VIQ score, relative to children living in a non-fluoridated region (Table 1; Fig. S1).

Water fluoride concentration was correlated with MUF ($r = 0.37$, $p < .001$) and estimated fluoride intake from formula ($r = 0.79$, $p < .001$); MUF was correlated with fluoride intake from formula ($r = 0.55$, $p < .001$).

3.1. Feeding status

The mean duration of exclusive breastfeeding was 4.98 months ($SD = 3.48$); 54 (13.6%) women reported never breastfeeding, 32 (8%) reported discontinuing breastfeeding after the first three months, and 200 (50.2%) reported continuing to breastfeed at six months or longer. Water fluoride concentration did not significantly differ between the BF ($M = 0.32$ mg/L) and FF groups ($M = 0.29$ mg/L; $p = .18$).

3.2. Model 1: IQ scores and water fluoride concentration by feeding status

A 0.5 mg/L increase in water fluoride concentration was associated with a decrease of 4.4 FSIQ points (95% CI: -8.34 , -0.46 , $p = .03$) in the FF group, but it was not significantly associated with FSIQ in the BF group ($B = -1.34$, 95% CI: -5.04 , 2.38 , $p = .48$) (Table 2; Fig. 1A); the interaction between water fluoride and feeding status was not statistically significant ($p = .26$). Controlling for fetal exposure by adding MUF to the model resulted in non-significant associations between water fluoride concentration and FSIQ in both the FF ($B = -3.58$, 95% CI: -7.83 , 0.66 , $p = .098$) and BF groups ($B = -1.69$, 95% CI: -5.66 , 2.27 , $p = .40$). Removing two cases with extreme IQ scores from the models resulted in non-significant associations between water fluoride concentration and FSIQ in both groups (Table S3).

Water fluoride concentration was significantly associated with lower PIQ in the FF ($B = -9.26$, 95% CI: -13.77 , -4.76 , $p < .001$) and the BF groups ($B = -6.19$, 95% CI: -10.45 , -1.94 , $p = .004$)

Abbreviations: FI = fluoride; MUF = maternal urinary fluoride; Regression model adjusted for maternal education (binary), maternal race (binary), child's age at IQ testing (continuous), child's sex, HOME total score (continuous), and second-hand smoke status in the child's house (yes, no).

* $p < .05$.

^a MUF was not significantly associated with FSIQ score ($B = -1.08$, 95% CI: $-1.54, 0.47$, $p = .29$), PIQ score ($B = -1.31$, 95% CI: $-3.63, 1.03$, $p = .27$), or VIQ score ($B = -0.34$, 95% CI: $-2.21, 1.59$, $p = .73$). Note: regression coefficients represent the predicted IQ difference per 0.5 mg/L MUF; effect for both sexes is reported. Variance inflation factor (VIF) for water FI is 2.41 for FSIQ, 2.41 for PIQ, and 2.40 for VIQ when MUF is entered in the model.

^b MUF is significantly associated with PIQ score ($B = -2.38$, 95% CI: $-4.62, -0.27$, $p = .04$), but not FSIQ score ($B = -1.50$, 95% CI: $-3.41, 0.43$, $p = .13$) or VIQ score ($B = -0.11$, 95% CI: $-1.94, 1.74$, $p = .91$). Note: regression coefficients represent the predicted IQ difference per 0.5 mg/L MUF; effect for both sexes is reported. Variance inflation factor (VIF) for infant fluoride intake is 1.10 for FSIQ, 1.12 for PIQ, and 1.10 for VIQ when MUF is entered in the model.

Fig. 1. A. Water fluoride concentration as a predictor of Full Scale IQ with an interaction by formula-fed (FF) vs. breastfed (BF) group. Black data points represent the FF group and grey data points represent the BF group. B. Fluoride intake from formula (mg F/day) as a predictor of Performance IQ score.

(Table 2); the interaction was not significant ($p = .26$). Controlling for MUF, water fluoride concentration remained significantly associated with PIQ in the FF ($B = -7.93$ 95% CI: $-12.84, -3.01, p = .002$) and BF groups ($B = -6.30$, 95% CI: $-10.92, -1.68, p = .008$). Likewise, the associations between water fluoride concentration and PIQ remained significant for both groups after removing two cases with extreme IQ scores (Table S3).

In contrast, water fluoride concentration was not associated with VIQ in the FF ($B = 0.89$, 95% CI: $-2.87, 4.65, p = .64$) or BF group ($B = 3.06$, 95% CI: $-0.49, 6.61, p = .09$); these associations remained non-significant after controlling for MUF (Table 2) and removing two cases with extreme IQ scores (Table S3).

3.3. Model 2: IQ scores and fluoride intake from formula

Fluoride intake from formula was not significantly associated with FSIQ ($B = -2.69$, 95% CI: $-7.38, 2.01, p = .26$) or VIQ ($B = 3.08$, 95% CI: $-1.40, 7.55, p = .18$) (Table 2). In contrast, a 0.5 mg increase in fluoride intake predicted an 8.76-point decrement in PIQ score (95% CI: $-14.18, -3.34, p = .002$; Fig. 1B). Adding MUF to the PIQ model slightly attenuated the association between fluoride intake and PIQ ($B = -7.62$, 95% CI: $-13.64, -1.60, p = .01$) (Table 2). Removing two cases with extreme IQ scores did not appreciably alter the association between fluoride intake and PIQ score, with and without adjustment for MUF (Table S3).

4. Discussion

For each 0.5 mg/L increase in water fluoride concentration, we found a decrease of 4.4 FSIQ points among preschool children who were formula-fed in the first six months of life; 0.5 mg/L is the approximate difference in mean water fluoride level between fluoridated (0.59 mg/L) and non-fluoridated (0.13 mg/L) regions. In contrast, we did not find a significant association between water fluoride concentration and FSIQ among exclusively breastfed children. The association between water fluoride concentration and FSIQ must be interpreted with caution, however, because the association became non-significant when two outliers were removed. We observed an even stronger association between water fluoride and PIQ (non-verbal intelligence). A 0.5 mg/L increase in water fluoride level predicted a decrement in PIQ in both the formula-fed (9.3-points) and the breastfed groups (6.2-points). Adjusting for fetal exposure or removing two extreme scores did not appreciably alter these results.

We observed converging results using fluoride intake from formula, which is a continuous, time-weighted exposure estimate. For each 0.5 mg/day of fluoride intake, we found an 8.8-point decrement in PIQ; adjusting for fetal exposure using MUF attenuated the association only slightly (7.6-point decrement in PIQ). MUF was also negatively associated with PIQ (2.4-point decrement for each 0.5 mg/L increase in MUF). The fluoride intake estimate may reflect a more refined measure of exposure in infancy because it captures differences in both water fluoride level and the proportion of time each child was given formula over the first year of life. Yet, our binary classification of whether a child was exclusively breastfed for 6 months may better capture children who are most vulnerable to neurotoxic effects of fluoride because it subsets those exposed to fluoride during the early infancy period when the brain undergoes significant development (Huttenlocher and Dabholkar, 1997; Kostovic, 2006). Taken together, these findings suggest that using optimally fluoridated water (0.7 mg/L) to reconstitute infant formula may diminish the development of intellectual abilities in young children, particularly for non-verbal abilities. The findings also suggest that both prenatal and postnatal fluoride exposure affect the development of non-verbal intelligence to a greater extent than verbal intelligence. Prior studies examining prenatal exposure to fluoride and IQ showed a similar pattern (Bashash et al., 2017; Green et al., 2019).

Consistent with prior studies showing a positive effect of breastfeeding on cognition (Horta et al., 2015), children in the breastfed group had higher FSIQ and VIQ scores relative to the formula-fed group, regardless of fluoridation status (Table 1); higher education and income levels in the breastfed group likely accounts for part of this association (Walfisch et al., 2013). In contrast, the breastfed group did not differ significantly from the formula-fed group with respect to PIQ score. Children who lived in non-fluoridated regions showed higher PIQ scores than children who lived in fluoridated regions, though this difference was significant only for the formula-fed group, perhaps reflecting a higher vulnerability of nonverbal abilities to fluoride exposure in infancy.

Most studies of fluoride exposure from infant formula consumption have focused on risk for later development of dental enamel fluorosis (Brothwell and Limeback, 2003; Hong et al., 2006; Berg et al., 2011). Beyond fluorosis, the safety of fluoride exposure from infant formula has not been rigorously tested, despite warnings of overexposure (Diesendorf and Diesendorf, 1979). A recent study showed that up to 59% of infants younger than four months exceed the upper limit (0.1 mg/kg/day) (Institutes of Medicine, 1997) when optimally fluoridated water is used to reconstitute infant formula (Harriehausen et al., 2019); 33% and 14.3% of six- and nine-month old infants exceeded the upper limit threshold, respectively. Conversely, breastfed infants receive very low fluoride intake (generally less than 0.01 mg/L), even in communities with fluoridated water (Dabeka et al., 1986; Ekstrand, 1981; Fomon et al., 2000). Our estimate of fluoride intake (0.34 mg F/day) among formula-fed infants who live in a fluoridated region is an

underestimate of actual fluoride intake because we did not include fluoride from other sources, such as the fluoride found in the formula or foods; thus, the association between fluoride intake and IQ scores among formula-fed infants may be stronger than the association obtained in our analysis.

Our results, which showed that higher fluoride exposure in infancy was associated with diminished IQ scores in young children, are consistent with two longitudinal birth cohort studies. In one study involving 299 mother–child pairs living in Mexico City, there was a decrement of 3.2 IQ points in preschool aged children for every 0.5 mg/L of MUF level during pregnancy (Bashash et al., 2017). In the other study, which we conducted using the same Canadian cohort, we reported a decrement of 2.2 IQ points among preschool aged boys for every 0.5 mg/L of MUF level during pregnancy (Green et al., 2019). When MUF was included as a covariate in the current study, the association between MUF and FSIQ was not significant (see Table 2, note a). This discrepancy arises because (1) Green et al. (2019) did not include fluoride exposure in infancy as a covariate and (2) Green et al. (2019) estimated sex-specific MUF effects whereas the current study estimated an overall MUF effect.

The beneficial effects of fluoride predominantly occur at the tooth surface, after teeth have erupted (Limeback, 1999). Fluoride contributes to the prevention of dental caries primarily when it is topically applied to teeth, such as brushing with fluoridated toothpaste (Featherstone, 2001; Limeback, 1999; NRC, 2006; Pizzo et al., 2007; Warren and Levy, 2003). Because fluoride is not essential for growth and development (Scientific Committee on Health and Environmental Risks (SCHER), 2011), there is no recommended intake level of fluoride during fetal development or in the first six months of life before teeth have erupted. Accordingly, the Canadian Pediatric Society recommends administering supplemental fluoride (i.e. systemic exposure) only when primary teeth begin to erupt (American Dental Association) (at approximately 6 months) and only if the child is susceptible to high caries activity and is not exposed to other fluoride-based interventions, such as toothbrushing or water fluoridation (Godel, 2002).

The American Dental Association (Berg et al., 2011; American Dental Association, 2018) advises parents to use optimally fluoridated drinking water to reconstitute concentrate infant formulas, while being cognizant of the potential risk of mild enamel fluorosis development. This recommendation is echoed by the Centers for Disease Control and Prevention (Community Water Fluoridation. Infant Formula) as well as the U.S. Department of Health and Human Services (2015). The Canadian Dental Association (2019) recommends using water with low fluoride concentration (or ready-to-feed formula) when the fluoride level in drinking water is above the optimal level. In addition to tap water, which is reportedly used by 93% of caregivers who feed formula to infants (Brothwell and Limeback, 2003), “nursery” water (which may contain up to 0.7 mg F/L) is marketed for reconstituting formula and sold in Canada and the United States. The availability of fluoridated nursery water gives the false impression that fluoride exposure during early infancy is beneficial prior to teeth eruption.

Formula-fed infants who reside in fluoridated areas have a 70-fold higher intake of fluoride than exclusively breastfed infants (Ekstrand, 1981; Zohoori et al., 2018; United States Environmental Protection Agency, 2010). Formula-fed infants also retain more fluoride than breastfed infants (Zohoori et al., 2018; Ekstrand and Hardell, 1984) because infants have a limited capacity to excrete fluoride before renal function reaches its full capacity at about two years of age (National Research Council (NRC), 2006; Zohoori et al., 2018). Fluoride absorption also depends on the presence of other nutrients (Health Canada, 2010); when fluoride intake is exclusively from reconstituted formula, the bioavailability of fluoride is 65%, whereas a varied diet reduces fluoride absorption in tissues and bone to about 47% (Ekstrand and Ehrnebo, 1979). These factors place formula-fed infants at an even higher risk of fluoride toxicity.

Our study has some limitations. First, infant formulas vary in

fluoride content. Ready-to-use formulas typically have less fluoride than powdered formula (Dabeka and McKenzie, 1987; Fomon et al., 2000); information about formula type was only available for 100 of 198 (50.5%) participants in the formula group; of those, 75% reported using powdered formula, which is the most common type of formula used by the general population (Infant Feeding Practices Survey II; Fomon et al., 2000). Variability in fluoride content is also seen across different types of powdered formula (United States Environmental Protection Agency, 2010; Harriehausen et al., 2019; Mahvi et al., 2010). Additionally, soy-based formula reconstituted with distilled water has more fluoride (0.24–0.30 mg/L depending on whether it is ready-to-feed or concentrated) than milk-based powdered formulas (0.12–0.17 mg/L) (Harriehausen et al., 2019; Van Winkle et al., 1995). Although we lacked data on brand of formula, we have no reason to expect that use of powdered versus ready-to-feed or soy- versus milk-based formula would differ by fluoridation status. Moreover, our effects were primarily based on water fluoride content, which is the major source of fluoride (Buzalaf et al., 2001). Second, we did not have specific information on the type of water (bottled versus tap) used to reconstitute formula. However, mothers typically report using tap water for reconstituting formula (Van Winkle et al., 1995) and we only included children of women who reported drinking tap water in our analyses. Third, there is potential for non-differential misclassification of the feeding status variable because mothers may have been confused by the definition of exclusive breastfeeding on the questionnaire or the responses may have been affected by recall or response bias. As with any survey, women could be confused by the question, but given the demographic of the sample – highly educated, English speaking, and non-teenage mothers – confusion seems less likely. Fourth, our method of estimating infant fluoride intake has not been validated. Finally, children were tested between 3 and 4 years of age and we have no information regarding other possible sources of fluoride that occurred between post-weaning and the age of testing. Thus, other sources of fluoride (e.g. dental products) or more frequent brushing, might differ between participants who lived in fluoridated versus non-fluoridated communities or among those in the breastfeeding versus formula-feeding group. To control for these potential differences, we included maternal education in all models. In addition, the design of our study compares water fluoride level and IQ scores in the formula-fed children using the breast-fed children as a control.

In summary, fluoride intake among infants younger than 6 months may exceed the tolerable upper limits if they are fed exclusively with formula reconstituted with fluoridated tap water. After adjusting for fetal exposure, we found that fluoride exposure during infancy predicts diminished non-verbal intelligence in children. In the absence of any benefit from fluoride consumption in the first six months, it is prudent to limit fluoride exposure by using non-fluoridated water or water with lower fluoride content as a formula diluent.

Funding source

This study was funded by a grant from the National Institute of Environmental Health Science (NIEHS) (grant #R21ES027044). The MIREC Study was supported by the Chemicals Management Plan at Health Canada, the Ontario Ministry of the Environment, and the Canadian Institutes for Health Research (grant #MOP-81285).

Financial disclosure

The authors have no financial disclosures.

Contributors statement

Dr Till conceptualized and designed the study, drafted the initial manuscript, and reviewed and revised the manuscript. Ms Green designed the study, curated the data, carried out the initial data analysis,

reviewed and revised the manuscript. Drs Flora and Hornung supervised data analysis, reviewed and revised the manuscript. Ms. Farmus assisted with data analysis, reviewed and revised the manuscript. Dr Martinez-Mier reviewed and revised the manuscript and supervised the analysis of maternal urinary fluoride. Mr Blazer collected the water fluoride data from water treatment plants and reviewed the manuscript. Drs Ayotte and Muckle assisted with initial data collection, and critically reviewed and revised the manuscript. Dr Lanphear conceptualized the study, and critically reviewed and revised the manuscript. All authors approved the final manuscript as submitted and agree to be accountable for all aspects of the work.

Declaration of Competing Interest

The authors declared that there is no conflict of interest.

Acknowledgements

The authors gratefully acknowledge: Nicole Lupien, Stéphanie Bastien, and Romy-Leigh McMaster and the MIREC Study Coordinating Staff for their administrative support, as well as the MIREC study group of investigators and site investigators; the INSPQ for measuring the urinary creatinine; Christine Buckley, Dr. Frank Lippert and Prithvi Chandrappa for their analysis of urinary fluoride at the Indiana University School of Dentistry; and Dr. John Minnery for his valuable engineering advice regarding water fluoridation. The authors are also grateful to the staff affiliated with community water treatment plants who helped to provide water fluoride data for this study.

BACKGROUND: Some evidence suggests that fluoride may be neurotoxic to children. Few of the epidemiologic studies have been longitudinal, had individual measures of fluoride exposure, addressed the impact of prenatal exposures or involved more than 100 participants.

OBJECTIVE: Our aim was to estimate the association of prenatal exposure to fluoride with offspring neurocognitive development.

METHODS: We studied participants from the Early Life Exposures in Mexico to Environmental Toxicants (ELEMENT) project. An ion-selective electrode technique was used to measure fluoride in archived urine samples taken from mothers during pregnancy and from their children when 6–12 y old, adjusted for urinary creatinine and specific gravity, respectively. Child intelligence was measured by the General Cognitive Index (GCI) of the McCarthy Scales of Children's Abilities at age 4 and full scale intelligence quotient (IQ) from the Wechsler Abbreviated Scale of Intelligence (WASI) at age 6–12.

RESULTS: We had complete data on 299 mother–child pairs, of whom 287 and 211 had data for the GCI and IQ analyses, respectively. Mean (SD) values for urinary fluoride in all of the mothers ($n=299$) and children with available urine samples ($n=211$) were 0.90 (0.35) mg/L and 0.82 (0.38) mg/L, respectively. In multivariate models we found that an increase in maternal urine fluoride of 0.5 mg/L (approximately the IQR) predicted 3.15 (95% CI: –5.42, –0.87) and 2.50 (95% CI: –4.12, –0.59) lower offspring GCI and IQ scores, respectively.

CONCLUSIONS: In this study, higher prenatal fluoride exposure, in the general range of exposures reported for other general population samples of pregnant women and nonpregnant adults, was associated with lower scores on tests of cognitive function in the offspring at age 4 and 6–12 y. <https://doi.org/10.1289/EHP655>

Introduction

Community water, salt, milk, and dental products have been fluoridated in varying degrees for more than 60 y to prevent dental caries, while fluoride supplementation has been recommended to prevent bone fractures (Jones et al. 2005). In addition, people may be exposed to fluoride through the consumption of naturally contaminated drinking water, dietary sources, dental products, and other sources (Doull et al. 2006). Whereas fluoride is added to drinking water [in the United States at levels of 0.7–1.2 mg/L (Doull et al. 2006)] to promote health, populations with exceptionally high exposures, often from naturally contaminated drinking water, are at risk of adverse health effects, including fluorosis.

In the United States, the U.S. Environmental Protection Agency (EPA) is responsible for establishing maximum permissible concentrations of contaminants, including fluoride, in public drinking-water systems. These standards are guidelines for restricting the amount of fluoride contamination in drinking water, not

standards for intentional drinking-water fluoridation. In 2006 the U.S. EPA asked the U.S. National Research Council (NRC) to reevaluate the existing U.S. EPA standards for fluoride contamination, including the maximum contaminant level goal (MCLG, a concentration at which no adverse health effects are expected) of 4 mg/L, to determine if the standards were adequate to protect public health (Doull et al. 2006). The committee concluded that the MCLG of 4 mg/L should be lowered because it puts children at risk of developing severe enamel fluorosis, and may be too high to prevent bone fractures caused by fluorosis (Doull et al. 2006). The Committee also noted some experimental and epidemiologic evidence suggesting that fluoride may be neurotoxic (Doull et al. 2006).

The National Toxicology Program (NTP) recently reviewed animal studies on the effects of fluoride on neurobehavioral outcomes and concluded that there was a moderate level of evidence for adverse effects of exposures during adulthood, a low level of evidence for effects of developmental exposures on learning and memory, and a need for additional research, particularly on the developmental effects of exposures consistent with those resulting from water fluoridation in the United States (Doull et al. 2006; NTP 2016). Human studies have shown a direct relationship between the serum fluoride concentrations of maternal venous blood and cord blood, indicating that the placenta is not a barrier to the passage of fluoride to the fetus (Shen and Taves, 1974). Fluoride was shown to accumulate in rat brain tissues after chronic exposures to high levels, and investigators have speculated that accumulation in the hippocampus might explain effects on learning and memory (Mullenix et al. 1995). An experimental study on mice has shown that fluoride exposure may have adverse effects on neurodevelopment, manifesting as both cognitive and behavioral abnormalities later in life (Liu et al. 2014).

Most epidemiologic studies demonstrating associations between fluoride exposure and lower neuropsychological indicators have been conducted in populations living in regions with endemic fluorosis that are exposed to high levels of fluoride in contaminated drinking water. The epidemiologic evidence is limited, however, with most studies using an ecologic design to estimate childhood exposures based on neighborhood measurements of fluoride (e.g., drinking water levels) rather than personal exposure measures. Moreover, almost all existing studies of childhood outcomes are cross-sectional in nature, rendering them weak contributors towards causal inference.

The main objective of this study was to assess the potential impact of prenatal exposures to fluoride on cognitive function and test hypotheses related to impacts on overall cognitive function. We hypothesized that fluoride concentrations in maternal urine samples collected during pregnancy, a proxy measure of prenatal fluoride exposure, would be inversely associated with cognitive performance in the offspring children. Overall, to our knowledge, this is one of the first and largest longitudinal epidemiologic studies to exist that either address the association of early life exposure to fluoride to childhood intelligence or study the association of fluoride and cognition using individual biomarker of fluoride exposure.

Methods

This is a longitudinal birth cohort study of measurements of fluoride in the urine of pregnant mothers and their offspring (as indicators of individual prenatal and postnatal exposures to fluoride, respectively) and their association with measures of offspring cognitive performance at 4 and 6–12 y old. The institutional review boards of the National Institute of Public Health of Mexico, University of Toronto, University of Michigan, Indiana University, and Harvard T.H. Chan School of Public Health and participating clinics approved the study procedures. Participants were informed of study procedures prior to signing an informed consent required for participation in the study.

Participants

Mother–child pairs in this study were participants from the successively enrolled longitudinal birth cohort studies in Mexico City that comprise the Early Life Exposures in Mexico to Environmental Toxicants (ELEMENT) project. Of the four ELEMENT cohorts [that have been described elsewhere (Afeiche et al. 2011)], Cohort 1 and Cohort 2B recruited participants at birth and did not have archived maternal-pregnancy urine samples required for this analysis; they were thus excluded. Mothers for Cohort 2A ($n = 327$) and 3 ($n = 670$) were all recruited from the same three hospitals in Mexico City that serve low-to-moderate income populations. Cohort 2A was an observational study of prenatal lead exposure and neurodevelopmental outcomes in children (Hu et al. 2006). Women who were planning to become pregnant or were pregnant were recruited during May 1997–July 1999 and were considered eligible if they consented to participate; were ≤ 14 wk of gestation at the time of recruitment; planned to stay in the Mexico City study area for at least 5 y; did not report a history of psychiatric disorders, high-risk pregnancies, gestational diabetes; did not report current use of daily alcohol, illegal drugs, and continuous prescription drugs; and were not diagnosed with preeclampsia, renal disease, circulatory diseases, hypertension, and seizures during the index pregnancy.

Cohort 3 mothers were pregnant women (≤ 14 wk of gestation) recruited from 2001 to 2003 for a randomized trial of the effect of calcium supplementation during pregnancy on maternal

blood lead levels (Ettinger et al. 2009). Eligibility criteria were the same as for Cohort 2A, and 670 agreed to participate.

Exposure Assessment

By virtue of living in Mexico, individuals participating in the study have been exposed to fluoridated salt (at 250 ppm) (Secretaría-de-Salud 1995, 1996) and to varying degrees of naturally occurring fluoride in drinking water. Previous reports, based on samples taken from different urban and rural areas, indicate that natural water fluoride levels in Mexico City may range from 0.15 to 1.38 mg/L (Juárez-López et al. 2007; Martínez-Mier et al. 2005). Mean fluoride content for Mexico City's water supply is not available because fluoride is not reported as part of water quality control programs in Mexico.

Mother–child pairs with at least one archived urine sample from pregnancy and measures of neurocognitive function in the offspring were included in this study. In terms of when the archived samples were collected, the pregnant mothers were invited for assessments with the collection of samples during trimester 1 (13.6 ± 2.1 wk for Cohort 3 and 13.7 ± 3.5 wk for Cohort 2A), trimester 2 (25.1 ± 2.3 wk for Cohort 3 and 24.4 ± 2.9 wk for Cohort 2A), and trimester 3 (33.9 ± 2.2 wk for Cohort 3 and 35.0 ± 1.8 wk for Cohort 2A).

A spot (second morning void) urine sample was targeted for collection during each trimester of pregnancy of ELEMENT mothers as well as the offspring children at the time of their measurements of intelligence at 6–12 y old. The samples were collected into fluoride-free containers and immediately frozen at the field site and shipped and stored at -20°C at the Harvard T. H. Chan School of Public Health (HSPH), and then at -80°C at the University of Michigan School of Public Health (UMSPH).

A procedure for urine analysis of fluoride described elsewhere (Martínez-Mier et al. 2011) was adapted and modified for this study. The fluoride content of the urine samples was measured using ion-selective electrode-based assays. First, 3 M sulfuric acid saturated with hexamethyldisiloxane (HMDS) was added to the sample to allow fluoride to diffuse from the urine for 20–24 hr. The diffused fluoride was allowed to collect in 0.05 M of sodium hydroxide on the interior of the petri dish cover. Once the diffusion was complete, 0.25 M of acetic acid was added to the sodium hydroxide to neutralize the solution and then analyzed directly using a fluoride ion-selective electrode (Thermo Scientific Orion, Cat#13-642-265) and pH/ISE meter (Thermo Scientific Orion, Cat#21-15-001). All electrode readings (in millivolts) were calculated from a standard curve. Analyses were performed in a Class 100/1,000 clean room. Quality control measures included daily instrument calibration, procedural blanks, replicate runs, and the use of certified reference materials (Institut National de Santé Publique du Québec, Cat #s 0910 and 1007; NIST3183, Fluoride Anion Standard). Urinary fluoride concentrations were measured at the UMSPH and the Indiana University Oral Health Research Institute (OHRI) as previously described (Thomas et al. 2016). A validation study comparing measures taken by the two labs in the same samples revealed a between-lab correlation of 0.92 (Thomas et al. 2016).

There were a total of 1,484 prenatal samples measured at the UMSPH lab. All of these samples were measured in duplicate. Of these, 305 (20%) of them did not meet the quality control criteria for ion-selective electrode-based methods (i.e., $\text{RSD} < 20\%$ for samples with $\text{F level} < 0.2$ ppm or $\text{RSD} < 10\%$ when $\text{F level} > 0.2$ ppm) (Martínez-Mier et al. 2011). Of these 305, 108 had a second aliquot available and were successfully measured at the OHRI lab in Indiana (sufficient urine volume was not available for the remaining 197 samples). The OHRI lab in Indiana also measured an additional 289 samples. Of the 397

total samples measured at the OHRI lab in Indiana, 139 (35%) were measured in duplicate, for which >95% complied with the quality control criteria above; thus, all 139 values were retained. The remaining 258 (65%) were not measured in duplicate because of limitations in available urine volume, but were included in the study given the excellent quality control at the OHRI lab. In total, we ended up with 1,576 prenatal urine samples with acceptable measures of fluoride.

Of these 1,576 urine samples, 887 also had data on urinary creatinine and were associated with mother–offspring pairs who had data on the covariates of interest and GCI or IQ in the offspring. The urinary creatinine data were used to correct for variations in urine dilution at the time of measurement (Baez et al. 2014). Creatinine-adjusted urinary fluoride concentrations were obtained for each maternally derived sample by dividing the fluoride concentration (MUF) in the sample by the sample's creatinine concentration (MUC), and multiplying by the average creatinine concentration of samples available at each trimester ($MUC_{average}$) using the formula: $(MUF/MUC) \times MUC_{average}$. The values of average creatinine concentration used for the $MUC_{average}$ at each trimester were derived from the larger pool of trimester-1, -2, and -3 samples from Cohorts 2A and 3 examined in our previous report on maternal fluoride biomarker levels (Thomas et al. 2016): 100.81, 81.60, and 72.41 (mg/L), respectively. For each woman, an average of all her available creatinine-adjusted urinary fluoride concentrations during pregnancy (maximum three samples and minimum one sample) was computed and used as the exposure measure (MUF_{cr}). For children, as creatinine measurements were not available, urinary fluoride values (CUF) were corrected for specific gravity (SG) using the formula $CUF_{sg} = CUF(1.02 - 1)/(SG - 1)$ (Usuda et al. 2007).

After calculating MUF_{cr} for the 887 urine samples noted above, 10 values of MUF_{cr} were identified as extreme outliers (>3.5 SDs) and were dropped, leaving 877 measures of MUF_{cr} . These 877 measures of MUF_{cr} stemmed from 512 unique mothers. Of these 512, 71 participants had measurements from each of the three trimesters; 224 had measurements from two of the three trimesters (74, T1 and T2; 131, T1 and T3; and 19, T2 and T3); and 217 had measurements from only one of the trimesters (159, T1; 34, T2; and 24, T3).

Measurement of Outcomes

At age 4 y, neurocognitive outcomes were measured using a standardized version of McCarthy Scales of Children's Abilities (MSCA) translated into Spanish (McCarthy 1991). MSCA evaluates verbal, perceptual-performance, quantitative, memory, and motor abilities of preschool-aged children, and it has previously been successfully used in translated versions (Braun et al. 2012; Julvez et al. 2007; Kordas et al. 2011; Puertas et al. 2010). For this analysis, we focused on the General Cognitive Index (GCI), which is the standardized composite score produced by the MSCA (McCarthy 1991). For children 6–12 y old a Spanish-version of the Wechsler Abbreviated Scale of Intelligence (WASI) (Wechsler 1999) was administered. WASI includes four subtests (Vocabulary, Similarities, Block Design, and Matrix Reasoning), which provide estimates of Verbal, Performance, and Full-Scale IQ (Wechsler 1999). Both tests were administered by a team of three psychologists who were trained and supervised by an experienced developmental psychologist (L.S.). This team of three psychologists applied all of the McCarthy tests as well as the WASI-FSIQ tests. At the time of follow-up visits (age 4 and 6–12 y), each child was evaluated by one of the psychologists who was blind to the children's fluoride exposure. The inter-examiner reliability of the psychologists was

evaluated by having all three psychologists participate in assessments on a set of 30 individuals. For these 30, the inter-examiner reliability of the psychologists was evaluated by calculating the correlation in GCI scores by two of the psychologists with the scores of a third psychologist whom they observed applying the test in all three possible combinations with 10 participants for each observers–examiner pair (i.e., psychologist A (applicant) was observed by psychologist B and psychologist C; psychologist B (applicant) was observed by psychologist A and psychologist C; and psychologist C (applicant) was observed by psychologist A and psychologist B). The mean observer–examiner correlation was 0.99. All raw scores were standardized for age and sex (McCarthy 1991). Inter-examiner reliability was not examined on the WASI test.

Measurement of Covariates

Data were collected from each subject by questionnaire on maternal age (and date of birth), education, and marital status at the first pregnancy visit; on birth order, birth weight, and gestational age at delivery; and on maternal smoking at every prenatal and postnatal visit. Gestational age was estimated by registered nurses. Maternal IQ was estimated using selected subtests of the Wechsler Adult Intelligence Scale (WAIS)-Spanish (Information, Comprehension, Similarities, and Block Design), which was standardized for Mexican adults (Renteria et al. 2008; Wechsler et al. 1981). Maternal IQ was measured at the study visit 6 mo after birth or at the 12-mo visit if the earlier visit was not completed.

The quality of the children's individual home environments was assessed using an age-appropriate version of the HOME score. However, the measure was not available for all observations because it was only added to on-going cohort evaluation protocols beginning in April 2003, when a version of the HOME score instrument that is age-appropriate for children 0–5 y old was adopted, following which a version of the HOME score instrument that is age-appropriate for children ≥6 y old was adopted in September 2009 (Caldwell and Bradley 2003). Thus, we adjusted for HOME score using the measures for 0- to 5-y-old children in the subset of children who had this data in our analyses of GCI, and we adjusted for HOME score using the measures for >6-y-old children in the subset of children who had this data in our analyses of IQ.

Statistical Analyses

Univariate distributions and descriptive statistics were obtained for all exposure variables, outcome variables, and model covariates. For each variable, observations were classified as outliers if they were outside the bounds of the mean ± 3.5 SDs. Primary analyses were conducted with exposure and outcome outliers excluded. Statistical tests of bivariate associations were conducted using chi-square tests for categorical variables and analysis of variance (ANOVA) to compare the means of the outcomes or exposure within groups defined according to the distribution of each covariate. Spearman correlation coefficients were used to measure the correlation between MUF_{cr} and CUF_{sg} . Regression models were used to assess the adjusted associations between prenatal fluoride and each neurocognitive outcome separately. Generalized additive models (GAMs) were used to visualize the adjusted association between fluoride exposure and measures of intelligence [SAS statistical software (version 9.4; SAS Institute Inc.)]. Because the pattern appeared curvilinear, and because GAMs do not yield exact *p*-values for deviations from linearity, we used a Wald *p*-value of a quadratic term of fluoride exposure to test the null hypothesis that a quadratic model fit the data better

STUDY SUBJECT INCLUSION FLOWCHART

STUDY BASE (Element Cohorts mothers recruited at trimester 1 of pregnancy; i.e. prenatal data available)

Figure 1. Flowchart describing source of mother-offspring subject pairs, fluoride and cognition study. Cohort 2A was designed as an observational birth cohort of lead toxicodynamics during pregnancy, with mothers recruited early during pregnancy from 1997 to 2001. Cohort 3 was designed as a randomized double-blind placebo-controlled trial of calcium supplements, with mothers recruited early during pregnancy from 2001 to 2006. “Ca” denotes subjects who were randomized to the calcium supplement; “placebo” denotes subjects who were randomized to the placebo. GCI is the McCarthy Scales General Cognitive Index (administered at age 4 y). IQ is the Wechsler Abbreviated Intelligence Scales Intelligence Quotient (administered at age 6–12 y and age-adjusted).

than the model assuming a linear relationship, and thus obtained a *p*-value for deviation from linearity of the fluoride–outcome associations. Residual diagnostics were used to examine other model assumptions and identify any additional potentially influential observations. Visual inspection of default studentized residual versus leverage plot from SAS PROC REG did not identify potential influential observations. Visual inspection of the histogram of the residuals did not indicate lack of normality; however, a fanning pattern in the residual versus predicted value plot indicated lack of constant variance (data not shown). Hence, robust standard errors were obtained using the “empirical” option in SAS PROC GENMOD.

Our overall strategy for selecting covariates for adjustment was to identify those that are well known to have potential associations with either fluoride exposure or cognitive outcomes and/or are typically adjusted for as potential confounders in analyses of environmental toxicants and cognition. All models were adjusted for gestational age at birth (in weeks), birthweight (kilograms), birth order (first born yes vs. no), sex, and child’s age at the time of the neurocognitive test (in years). All models were also adjusted for maternal characteristics including marital status (married vs. others), smoking history (ever-smoker vs. never-

smoker), age at delivery, IQ, and education (itself also a proxy for socioeconomic status). Finally, all models adjusted for potential cohort effects by including indicator variables denoting from which cohort (Cohort 2A, Cohort 3 + Ca supplement, and Cohort 3 -placebo) the participants came. We used 0.5 mg/L, which was close to the interquartile range of MUF_{cr} for the analyses of both GCI (IQR = 0.45) and IQ (IQR = 0.48), as a standard measure of incremental exposure. SAS statistical software (version 9.4; SAS Institute Inc.) was used for all data analyses described.

Sensitivity Analyses

Models were further adjusted for variables that relate to relatively well-known potential confounders (but for which we were missing a significant amount of data) and variables that were less-well known but possible confounders. The HOME scores were subject to sensitivity analyses because, as noted in the “Methods” section, they were not added to the subject evaluation protocols until 2003, resulting in a significantly smaller subsample of participants with this data. Models of the association between prenatal fluoride exposure (MUF_{cr}) and IQ at 6–12 y old were also adjusted for the child’s urine fluoride concentration at 6–12 y of

Table 1. Comparisons across cohorts with respect to the distributions of biomarkers of exposure to prenatal fluoride (MUF_{cr}), prenatal lead (maternal bone Pb), prenatal mercury (maternal blood Hg), and contemporaneous childhood fluoride (CUF_{sg}); and cognitive outcomes (GCI and IQ).

^aThe total number of subjects (*n* = 997) are all mother–offspring pairs who participated in the original Cohort 2A and Cohort 3 studies.

^bMaternal education at the time of the child's birth.

^cMaternal IQ measured at 6 mo after child's birth.

^dMother's marital status at the time of the child's birth.

^eHistory of any maternal smoking.

^fHOME score measured using the separate age-appropriate instruments pertaining to children of ≤ 5 y old; and children > 5 y old.

^gFamily socioeconomic status (SES) measured by questionnaire of family possessions at follow-up.

^hMaternal patella bone lead measured by KXRF after birth.

ⁱMaternal average blood mercury during pregnancy.

^jChildren's specific gravity–corrected urinary fluoride measured at the time of each child's IQ test (6–12 y old).

N[†] Number of subjects with measurements of MUF_{cr}, cognitive outcome, main covariates, and sensitivity covariates (they are included in the sensitivity model).

N[‡] Number of subjects with measurements of sensitivity covariates, but missing data on exposure, outcomes, or main covariates (they are excluded from the sensitivity model).

age (CUF_{sg}), a measure that was collected in a significantly smaller subset of individuals, to evaluate the potential role of contemporaneous exposure. Associations between prenatal fluoride exposure (MUF_{cr}) and GCI at 4 y old could not be adjusted for contemporaneous fluoride exposure because urine samples were not collected from children when the MSCA (from which the GCI is derived) was administered. Maternal bone lead measured by a 109-Cd K-X-ray fluorescence (KXRF) instrument at 1 mo postpartum, a proxy for lead exposure from mobilized maternal bone lead stores during pregnancy (Hu et al. 2006), was included in the model to test for the possible confounding effect of lead exposure during pregnancy. We focused on the subset of women who had patella bone lead values because these were found to be most influential on our previous prospective study of offspring cognition (Gomaa et al. 2002). Average maternal mercury level during pregnancy was also tested for being a potential confounder (Grandjean and Herz 2011). Mercury was measured as total mercury content in the subsample of women who had samples of archived whole blood samples taken during pregnancy

with sufficient volume to be analyzed using a Direct Mercury Analyzer 80 (DMA-80, Milestone Inc., Shelton, CT, USA) as previously described (Basu et al. 2014).

To address the potential confounding effect of socioeconomic status (SES) we conducted sensitivity analyses that adjusted our model for SES (family possession score). The socioeconomic questionnaire asked about the availability of certain items and assets in the home. Point values were assigned to each item, and SES was calculated based on the sum of the points across all items (Huang et al. 2016). Given that the calcium intervention theoretically could have modified the impact of fluoride, in examining our results, we repeated the analyses with and without the Cohort 3 participants who were randomized to the calcium intervention to omit any potential confounding effect of this intervention. Another sensitivity test was performed to examine the potential effect of the psychologist who performed the WASI test by including tester in the regression model. The information about psychologists who performed the WASI was available for 75% of participants, as recording this data was

^aMaternal creatinine-adjusted urinary fluoride (mg/L).^bHome Observation for the Measurement of the Environment (HOME) score, measured using the separate age-appropriate instruments pertaining to children of ≤5 y old; and children >5 y old.^cChild contemporaneous specific gravity-adjusted urinary fluoride (available at the time of each child's IQ test).

added later to the study protocol. We also re-ran models with exposure outliers included as a sensitivity step. Finally, we ran models that focused on the cross-sectional relationship between children's exposure to fluoride (reflected by CUF_{sg}) and IQ score, unadjusted; adjusting for the main covariates of interest; and adjusting for prenatal exposure (MUF_{cr}) as well as the covariates of interest.

Results

Flow of Participants

Of the 997 total mothers from two cohorts evaluated, 971 were eligible after removing mothers <18 y old. Of these 971, 825 had enough urine sample volume to measure fluoride in at least one trimester urine sample, and of these 825 participants, 515 participants had urine samples with previously measured creatinine values, enabling calculation of creatinine-adjusted urinary fluoride (MUF_{cr}) concentrations. Of these 515, 3 participants were excluded based on the 10 extreme outlier values identified for MUF_{cr} (see the "Methods" section, "Exposure Assessment" subsection) and not having any other MUF_{cr} values to remain in the analysis. Thus, we had a total of 512 participants (mothers) with at least one value of MUF_{cr} for our analyses (Figure 1).

Of these 512 mothers, 312 had offspring with outcome data at age 4 (i.e., GCI), and 234 had offspring with outcome data at age

6–12 (i.e., IQ). Of these, complete data on all the covariates of main interest (as specified in the "Methods" section) were available on 287 mother–child pairs for the GCI analysis and 211 mother–child pairs for the IQ analysis. A total of 299 mother–child pairs had data on either GCI or IQ, and 199 mother–child pairs had data on both GCI and IQ (Figure 1).

Number of Exposure Measures per Subject

In terms of repeated measures of MUF_{cr} across trimesters, of the 287 participants with data on GCI outcomes; 25 participants had MUF_{cr} data for all three trimesters (11 from Cohort 2A and 14 from Cohort 3), 121 participants had MUF_{cr} data from two trimesters (48 from Cohort 2A and 73 from Cohort 3), and 141 participants had MUF_{cr} data from one trimester (51 from Cohort 2A and 90 from Cohort 3). Of the 211 participants with data on IQ outcomes, 10 participants had MUF_{cr} data for all three trimesters (6 from Cohort 2A and 4 from Cohort 3), 82 participants had data from two trimesters (32 from Cohort 2A and 50 from Cohort 3), and 119 participants had data from one trimester (40 from Cohort 2A and 79 from Cohort 3).

Comparisons across the Cohorts

In terms of the mother–child pairs who had data on all covariates as well as data on either GCI or IQ (*n* = 299), the mean (SD)

^aCoefficients from linear regression models adjusted for gestational age, weight at birth, sex, parity (being the first child), age at outcome measurement, and maternal characteristics including smoking history (ever smoked during the pregnancy vs. nonsmoker), marital status (married vs. others), age at delivery, IQ, education, and cohort (Cohort 3-Ca, Cohort 3-placebo and Cohort 2A). Model A−HOME, model A for subset of cases who have data on Home Observation for the Measurement of the Environment (HOME) scores (but the model did not include HOME score). Model A + HOME, model A for subset of cases with HOME score, adjusted for HOME score. Model A −CUF_{sg}, model A for subset of cases who have data on child contemporaneous specific gravity-adjusted urinary fluoride CUF_{sg} (but the model did not include CUF_{sg}). Model A + CUF_{sg}, model A for subset of cases with CUF_{sg}, adjusted for CUF_{sg}. Model A −SES, model A for subset of cases who have data on socioeconomic status (family possession measured by questionnaire of family possessions) (but the model did not include SES). Model A + SES, model A for subset of cases with SES data, adjusted for SES. Model A−Pb, model A for subset of cases who have data on maternal bone lead (but the model did not include maternal bone lead). Model A + Pb, model A for subset of cases with data on maternal bone lead, adjusted for maternal bone lead. Model A −Hg, model A for subset of cases who have data on maternal blood mercury (but the model did not include maternal blood mercury). Model A + Hg, model A for subset of cases who have data on maternal blood mercury, adjusted for maternal blood mercury. Model A −Ca, model A for subset of cases who did not receive the Ca supplement (they received the placebo).

values of creatinine-corrected urinary fluoride for the mothers was 0.90 (0.36) mg/L. The distributions of the urinary fluoride, outcomes (GCI and IQ), and additional exposure variables examined in our sensitivity analyses (maternal bone lead, maternal blood mercury, and children's contemporaneous urinary fluoride) across the three cohort strata (Cohort 3-Calcium, Cohort 3-placebo, and Cohort 2A) and all strata combined are shown in Table 1 for the mother-child pairs who had data for the GCI outcome ($n=287$) and the IQ outcome ($n=211$). The distributions showed little variation across the cohort strata except for bone lead and possibly blood mercury, for which, in comparison with Cohort 3, Cohort 2A clearly had higher mean bone lead levels ($p < 0.001$) and possibly higher blood mercury levels ($p = 0.067$). The mean (SD) values of specific gravity-corrected urinary fluoride for the children who had these measures (only available for those children who had IQ; $n = 189$) were 0.82 (0.38) mg/L.

In terms of the comparability of the participants across Cohort 2A and Cohort 3 with respect to our covariates, the distribution of the covariates was very similar with the exception of age of the offspring when IQ was measured, for which the mean ages were 7.6 and 10.0 y, respectively; and birth weight in the GCI analysis, for which Cohort 3 participants were slightly heavier than Cohort 2 participants (see Table S1).

GCI versus IQ Scores

There was a significant correlation between GCI at 4 y and IQ at 6–12 y old (Spearman $r = 0.55$; $p < 0.01$). There was no significant correlation between prenatal MUF_{cr} and offspring CUF_{sg} (Spearman $r = 0.54$, $p = 0.44$).

Comparisons of Participants in Relation to Missing Data

In comparing the participants who were included for the GCI and IQ analyses with the participants who were not included (based on data missing on GCI, IQ or other covariates), the distribution of covariates were similar except for sex, for which the proportion of females was somewhat higher in the included versus excluded group for both the GCI and IQ analyses (Table 2).

In terms of the sensitivity analyses, for each sensitivity variable of interest, we compared participants who had data on our exposures, outcomes, covariates, and the sensitivity variable of interest (and were thus included in the sensitivity analysis) versus participants who had data on the sensitivity variable of interest but were missing data on the exposure, outcomes, and/or covariates of interest (and were thus excluded from the sensitivity analysis; Table 2). It can be seen that for each sensitivity analysis, most of the participants with data on the sensitivity variable of interest also had data on the exposures, outcomes, and covariates and were therefore included in the sensitivity analysis. In addition, the distributions appeared to be similar comparing those included with those excluded in each sensitivity analysis (means were within 10% of each other), with the exception of maternal blood Hg, for which the mean levels for those included were 28.5% and 24.9% higher than the mean levels for those excluded in the GCI and IQ analyses, respectively.

Comparisons of GCI and IQ across Covariates

Table 3 shows mean and SD values for MUF_{cr} and offspring cognitive scores across categories of the covariates. In the participants with GCI data, the offspring cognitive scores were higher among mothers with higher levels of education, measured IQ, and HOME scores for both analyses; and scores were higher among first children and girls. In the IQ analysis a statistically significant difference was observed in MUF_{cr} as a function of child sex. No significant differences in MUF_{cr} values across levels of other covariates were observed. A modest difference (not statistically significant), was observed in MUF_{cr} as a function of maternal IQ ($p = 0.09$), and MUF_{cr} as a function of child sex ($p = 0.09$). Among other co-variables there were significant differences in age ($p < 0.01$) in both analyses.

Regression Models of GCI

Before adjustment, a 0.5 mg/L increase in MUF_{cr} was negatively associated with GCI at 4 y old [mean score −3.76; 95% confidence interval (CI): −6.32, −1.19] (Table 4). The association was somewhat attenuated after adjusting for the main covariates

Figure 2. Adjusted association of maternal creatinine-adjusted urinary fluoride (MUF_{cr}) and General Cognitive Index (GCI) scores in children at age 4 y. Adjusted for gestational age, weight at birth, sex, parity (being the first child), age at outcome measurement, and maternal characteristics including smoking history (ever smoked vs. nonsmoker), marital status (married vs. others), age at delivery, IQ, education, and cohort (Cohort 3-Ca, Cohort 3-placebo and Cohort 2A). Shaded area is 95% confidence interval. Short vertical bars on the x-axis reflect the density of the urinary fluoride measures. Individual data points are individual observations, $n = 287$.

(model A, -3.15 ; 95% CI: -5.42 , -0.87). The smooth plot of the association between GCI and maternal prenatal urinary fluoride from an adjusted GAM model suggested a linear relation over the exposure distribution (Figure 2).

Regression Models of IQ

A 0.5 mg/L increase in prenatal fluoride was also negatively associated with IQ at age 6–12 y based on both unadjusted (-2.37 ; 95% CI: -4.45 , -0.29) and adjusted models (-2.50 ; 95% CI: -4.12 , -0.59) (Table 4). However, estimates from the adjusted GAM model suggest a nonlinear relation, with no clear association between IQ scores and values below approximately 0.8 mg/L, and a negative association above this value (Figure 3A). There was a nonsignificant improvement in the fit of the model when a quadratic term was added to the linear model ($p = 0.10$).

Sensitivity Analyses

In sensitivity analyses, adjustment for HOME score increased the magnitude of the association between MUF_{cr} and GCI, though the difference was less pronounced when associations with and without adjustment for HOME score were both estimated after restricting the model to the subset of 138 children with HOME score data (Table 4). The association of IQ scores with MUF_{cr} did not substantially change after adding HOME score to the model (Table 4).

The association between MUF_{cr} and IQ was attenuated slightly after adjusting for contemporaneous children's urinary fluoride (CUF_{sg}) and comparing estimates with $[-1.73$ (95% CI: -3.75 , 0.29)] and without $[-1.94$ (95% CI: -4.15 , 0.26)] adjustment for CUF_{sg} among the 189 children with this data (Table 4). In addition, the evidence of nonlinearity was more pronounced, with no clear evidence of an association for $MUF_{cr} < 1.0$ mg/L

Figure 3. (A) Adjusted association of maternal creatinine-adjusted urinary fluoride (MUF_{cr}) and children's IQ at age 6–12 y. Adjusted for gestational age, weight at birth, sex, parity (being the first child), age at outcome measurement, and maternal characteristics including smoking history (ever smoked vs. nonsmoker), marital status (married vs. others), age at delivery, IQ, education, and cohort (Cohort 3-Ca, Cohort 3-placebo and Cohort 2A). Short vertical bars on the x-axis reflect the density of the urinary fluoride measures. Individual data points are individual observation, $n = 211$. (B) Association of maternal creatinine-adjusted urinary fluoride (MUF_{cr}) and children's IQ at age 6–12 y, adjusted for specific gravity-adjusted child urinary fluoride (CUF_{sg}). Adjusted for gestational age, weight at birth, sex, parity (being the first child), age and CUF_{sg} at outcome measurement, and maternal characteristics including smoking history (ever smoked vs. nonsmoker), marital status (married vs. others), age at delivery, IQ, education, and cohort (Cohort 3-Ca, Cohort 3-placebo and Cohort 2A). Shaded area is 95% confidence interval. Short vertical bars on the x-axis reflect the density of the urinary fluoride measures. Individual data points are individual observation, $n = 189$.

based on the GAM model (Figure 3B), and a significant improvement in model fit when a quadratic term was added to the linear regression model ($p = 0.01$).

When we restricted models to subsets of children with available data for each additional covariate, there was little difference

between adjusted and unadjusted associations between MUF_{cr} and GCI or IQ when socioeconomic status (family possession), maternal bone lead, and blood mercury, were added to models (Table 4). However, the effect estimates associated with MUF_{cr} for these analyses appear to be higher in the subsets with available data for these variables.

Adding tester (psychologist who performed WASI) in the model did not substantially change the results (data not shown). In the sensitivity analyses in which we excluded Cohort 3 participants who received the calcium supplement, we continued to observe a negative association between MUF_{cr} and GCI [0.5 mg/L increase in MUF_{cr} associated with 3.67 lower GCI (95% CI: -6.57, -0.77), *n* = 194]; and between MUF_{cr} and IQ [0.5 mg/L increase in MUF_{cr} associated with 3.23-lower IQ (95% CI: -5.88, -0.57), *n* = 136].

In sensitivity analyses in which we re-ran models that included the 10 outliers with respect to fluoride exposure (for each of seven participants already in our models, an additional value of MUF_{cr} [from a different trimester]; for three participants, a value of MUF_{cr} that then allowed the participants to be added to our models), the results did not change in any meaningful way (data not shown). There were no outliers with respect to cognitive outcomes.

Independent Influence of Child Fluoride Exposure

Finally, in models that focused on the cross-sectional relationship between children's exposure to fluoride (reflected by their specific gravity-adjusted urinary fluoride levels) and IQ score and that contained the main covariates of interest, there was not a clear, statistically significant association between contemporaneous children's urinary fluoride (CUF_{sg}) and IQ either unadjusted or adjusting for MUF_{cr}. A 0.5 mg/L increase in CUF_{sg} was associated with a 0.89 lower IQ (95% CI: -2.63, 0.85) when not adjusting for MUF_{cr}; and 0.77-lower IQ (95% CI: -2.53, 0.99), adjusting for MUF_{cr} (*n* = 189).

Discussion

In our study population of Mexican women and children, which accounted for two of the three cohorts included in the ELEMENT study, higher prenatal exposure to fluoride (as indicated by average creatinine-adjusted maternal urinary fluoride concentrations during pregnancy) was associated with lower GCI scores in children at approximately 4 y old, and with lower Full-Scale IQ scores at 6–12 y old. Estimates from adjusted linear regression models suggest that mean GCI and IQ scores were about 3 and 2.5 points lower in association with a 0.5 mg/L increase in prenatal exposure, respectively. The associations with GCI appeared to be linear across the range of prenatal exposures, but there was some evidence that associations with IQ may have been limited to exposures above 0.8 mg/L. In general, the negative associations persisted in sensitivity analyses with further adjustment for other potential confounders, though the results of sensitivity analyses were based on subsets of the population with available data.

Overall, our results are somewhat consistent with the ecological studies suggesting children who live in areas with high fluoride exposure (ranging from 0.88 to 11.0 mg/L fluoride in water, when reported) have lower IQ scores than those who live in low-exposure or control areas (ranging from 0.20 to 1.0 mg/L fluoride in water) (Choi et al. 2012) and with results of a pilot study of 51 children (mean age 7 y) from southern Sichuan, China, that reported that children with moderate or severe dental fluorosis (60% of the study population) had lower WISC-IV digit span scores than other children (Choi et al. 2015). A distinction is that

our study, which was longitudinal with repeated measures of exposure beginning in the prenatal period, found associations with respect to prenatal fluoride exposures.

To our knowledge, the only other study that is similar to ours was only recently published. Valdez Jiménez et al. (2017) studied the association of prenatal maternal urinary fluoride levels (not corrected for dilution) and scores on the Bayley Scales of Infant Development II among 65 children evaluated at age 3–15 mo (average of 8 mo). The mothers in their study had urinary fluoride levels of which the means at each of the three trimesters of pregnancy (1.9, 2.0, 2.7 mg/L) were higher than the mean MUF_{cr} in our participants (0.88 mg/L) (Valdez Jiménez et al. 2017). These levels of exposure were found to be associated with statistically significantly lower scores on the Bayley Scales' Mental Development Index (MDI) score after adjusting for gestational age, age of child, a marginality index, and type of drinking water (Valdez Jiménez et al. 2017). By comparison, our study had much longer periods of follow-up and larger sample sizes, controlled for a much larger set of covariates and sensitivity variables, and used creatinine-corrected urinary fluoride measures (which, by adjusting for urinary dilution effects, provides a more reliable measure of internal fluoride exposure).

With respect to understanding the generalizability of our findings to other populations, there are very few studies that measured prenatal fluoride levels among women derived from population-based samples. Gedalia et al. (1959) measured urinary fluoride in multiple samples collected from each of 117 healthy pregnant women living in Jerusalem, where fluoride in the water was approximate 0.50 mg/L, and reported mean levels per person that ranged from 0.29 to 0.53 mg/L. However, these analysis were not conducted utilizing modern analytical techniques. In a study of 31 pregnant women living in Poland, Opydo-Szymaczek and Borysewicz-Lewicka (2005) measured urinary fluoride in healthy pregnant women patients of a maternity hospital in Poland, where fluoride in the water ranged from 0.4 to 0.8 mg/L, and found a mean level of 0.65 mg/L for women in their 28th week of pregnancy, 0.84 mg/L in their 33rd week, and 1.30 mg/L in healthy non-pregnant women of similar age. This would suggest that the mothers in our study, who had a mean MUF_{cr} value of 0.90 mg/L, had fluoride exposures slightly higher than prior-mentioned populations.

In terms of comparing our findings with other studies of fluoride (using urinary fluoride as a biomarkers of exposure) and intelligence (i.e., those not involving prenatal exposures), of the 27 epidemiologic studies on fluoride and IQ reviewed by Choi et al. in their 2012 meta-analysis, only 2 had measures of urinary fluoride. Both were of urinary fluoride measures in children (not pregnant mothers), and neither corrected for dilution (either by correcting for urinary creatinine or specific gravity). Of these two, in comparison with the urinary fluoride levels of both our mothers (0.88 mg/L) and our children (0.82 mg/L), the mean levels of children's urinary fluoride were higher in the non-fluorosis (1.02 mg/L) and high-fluorosis (2.69 mg/L) groups found by Li et al. (1995) as well as the control (1.5 mg/L) and high-fluorosis (5.1 mg/L) groups described by Wang et al. (2007).

Among the limitations of our study are that we measured fluoride in spot (second morning void) urine samples instead of 24-hr urine collections. However, others have noted a close relationship between the fluoride concentrations of early morning samples and 24-hr specimens (Watanabe et al. 1994; Zohouri et al. 2006). Another limitation relates to the potential differences in the distribution of covariates over our study cohorts, raising the issue of potential bias. In the analyses we conducted across cohorts, we saw that, in comparison with Cohort 3, Cohort 2A clearly had

higher mean bone lead levels ($p < 0.001$) and possibly higher blood mercury levels ($p = 0.067$). However, we saw no other differences and the differences in these measures have a clear likely explanation: Cohort 2A had bone lead levels measured in 1997–2001 and Cohort 3 had bone lead levels measured in 2001–2005. Given that environmental lead and mercury exposures were steadily decreasing during this time interval (due to the phase-out of lead from gasoline), this difference likely relates to an exposure–time–cohort effect. We do not anticipate that this phenomenon would have introduced a bias in our analyses of fluoride and cognition controlling for bone lead.

Another limitation relates to the missing data that pertain to our covariate and sensitivity variables. In the comparisons of participants in relation to missing data (Table 2A,B), the proportion of females was somewhat higher in the included versus excluded group for both the GCI and IQ analyses, and the mean levels of maternal blood Hg for those included were 28.5% and 24.9% higher than the mean levels for those excluded in the GCI and IQ analyses, respectively. We also note that the coefficients for the associations between fluoride on cognition varied substantially in some of the sensitivity analyses, particularly with respect to the subgroups of participants who have data on SES, lead exposure, and mercury exposure (of which, for the latter, the effect estimates almost doubled). We do not have a ready explanation for this phenomenon, given that there is no obvious way that each of the selection factors governing which mothers had these measurements (discussed above) could have influenced the fluoride–cognition relationship. Nevertheless, it is not possible to entirely rule out residual confounding or in the population as a whole (that might have been detected had we had full data on larger sample sizes) or bias (should the subpopulations that had the data for analysis have a different fluoride–cognition relationship than those participants who were excluded from the analyses).

Other limitations include the lack of information about iodine in salt, which could modify associations between fluoride and cognition; the lack of data on fluoride content in water given that determination of fluoride content is not reported as part of the water quality monitoring programs in Mexico; and the lack of information on other environmental neurotoxicants such as arsenic. We are not aware of evidence suggesting our populations are exposed to significant levels of arsenic or other known neurotoxicants; nevertheless, we cannot rule out the potential for uncontrolled confounding due to other factors, including diet, that may affect urinary fluoride excretion and that may be related to cognition.

Another potential limitation is that we adjusted maternal urinary fluoride levels based on urinary creatinine, whereas we adjusted children's urinary fluoride levels based on urinary specific gravity; however, these two methods are almost equivalent in their ability to account for urinary dilution. We also had no data to assess the inter-examiner reliability of the testers administering the WASI test; however, the excellent reliability of these same testers in administering the McCarthy tests provides some reassurance that the WASI tests were conducted in a consistent manner.

Finally, our ability to extrapolate our results to how exposures may impact on the general population is limited given the lack of data on fluoride pharmacokinetics during pregnancy. There are no reference values for urinary fluoride in pregnant women in the United States. The Centers for Disease Control and Prevention has not included fluoride as one of the population exposures measured in urine or blood samples in its nationally representative sampling. The WHO suggests a reference value of 1 mg/L for healthy adults when monitoring renal fluoride excretion in

community preventive programs (Marthaler 1999). As part of the NRC's review of the fluoride drinking-water standard, it was noted that healthy adults exposed to optimally fluoridated water had urinary fluoride concentrations ranging from 0.62 to 1.5 mg/L.

Conclusion

In this study, higher levels of maternal urinary fluoride during pregnancy (a proxy for prenatal fluoride exposure) that are in the range of levels of exposure in other general population samples of pregnant women as well as nonpregnant adults were associated with lower scores on tests of cognitive function in the offspring at 4 and 6–12 y old.

Community water and salt fluoridation, and fluoride toothpaste use, substantially reduces the prevalence and incidence of dental caries (Jones et al. 2005) and is acknowledged as a public health success story (Easley 1995). Our findings must be confirmed in other study populations, and additional research is needed to determine how the urine fluoride concentrations measured in our study population are related to fluoride exposures resulting from both intentional supplementation and environmental contamination. However, our findings, combined with evidence from existing animal and human studies, reinforce the need for additional research on potential adverse effects of fluoride, particularly in pregnant women and children, and to ensure that the benefits of population-level fluoride supplementation outweigh any potential risks.

COMMENT & RESPONSE

In Reply We appreciate the widespread interest in our study and the opportunity to respond to the critiques and clarify some facts.

1. Fundamentals of epidemiology | We agree that our study reported an association, not causation. Still, observational studies are optimal for testing many important questions in public health, and they are often used to infer causality. Indeed, if we dismissed observational studies, we would have no evidence that water fluoridation prevents tooth decay in children.

Several commentators raised questions about the effect of residual confounding. Our results, as with all observational studies, are subject to confounding by unmeasured factors. Still, we considered many potential confounders. Unless unmeasured factors are identified and shown to be associated with both fluoride exposure and IQ, these criticisms are speculative.

Our conclusions did not “simply rely on *P* values.” We established our hypotheses *a priori*, carefully interpreted effect estimates and confidence intervals, conducted a comprehensive set of sensitivity analyses, acknowledged the limitations of our study, and considered the results of other studies before concluding that pregnant women should reduce their fluoride intake.

Others were concerned about imprecise results. Keep in mind that (1) the fitted regression line is covariate-adjusted, whereas individual data points in the figure are not, and (2) individual data points close to the regression line may represent numerous overlapping cases. Also, the outliers in our data set have low influence but good leverage because their inclusion improves the estimate’s precision. Nonetheless, we ran secondary analyses without the 2 very low IQ scores and the fluoride effect remained.

2. This is not a subtle finding | Is a 4.5 IQ decrement per 1 mg/L increase in urinary fluoride weak? A decrement of 4.5 IQ points among many boys can have a substantial effect on the population distribution of IQ scores.¹ With 14% of Canadian women living in fluoridated regions having urinary fluoride of at least 1 mg/L, we would expect even larger IQ decrements for some children.

Our study is consistent with other high-quality research; it is not a standalone study. More than 50 studies have shown an association between higher fluoride exposure and lower IQ. All 3 prospective birth cohort studies^{2,3} reported that higher prenatal fluoride exposure led to lower IQ scores in children.

3. Clarifying misconceptions | We did not set out to compare IQ scores in children who lived in fluoridated vs nonfluoridated communities. We used a biomarker of fluoride exposure that

accounts for all sources. However, we did find consistent IQ decrements associated with fluoride intake and water fluoride concentrations.

Some commentators were troubled by the reported sex differences. Male individuals are often more susceptible to toxicants, including prenatal fluoride exposure in some animal studies.⁴ Moreover, the National Toxicology Program (2016) called for sex-based analyses for fluoride.⁵ Thus, we planned to test sex differences. We thank Waugh for his suggestion that male mitochondria may be more sensitive to fluoride.

Blendoe et al suggest that the IQ differences are explained by sex differences. Sex differences in IQ scores do not explain the exposure-response association that we observed in boys using urinary fluoride concentrations.

We collected 3 urine samples (1 for each trimester) and adjusted them for urinary dilution, an improvement over other population-based studies on fluoride neurotoxicity. Urinary fluoride is not a perfect measure of fluoride intake, but it is reliable, and it is the optimal biomarker of concurrent fluoride exposure.⁶

We cited a dental fluorosis prevalence rate of 68% in adolescents based on a prior study using National Health and Nutrition Examination Survey data. As noted by Gehani et al, the quality of these data was assessed in an April 2019 report. The prevalence of fluorosis, which is now estimated to be 41%,⁷ is still considerably higher than when water fluoridation was introduced.

We acknowledge that IQ tests have been criticized as having cultural biases. However, our analyses did not compare groups that differed by culture. Moreover, we controlled for ethnicity and city.

Finally, several commentators requested results that we did not report in our manuscript. We endeavor to make our analyses as transparent as possible and have posted supplemental material on the Open Science Framework (<https://osf.io/7vfu5>). Access to the data to validate our findings is available to independent researchers who adhere to the MIREC Biobank policies outlined here: <http://www.mirec-canada.ca/en/research/>.

We agree with Howard et al. Ten years ago, many of the same criticisms, such as bias, imprecision, unmeasured confounding and subtle effects, were raised about studies of low-level lead toxicity.

To conclude, some commentators argued that studies that showed fluoride diminishes children’s intellectual abilities should be interpreted cautiously. We agree. We should also take precautions to protect children’s brains from a potential toxicant, especially when there is no benefit of fluoride for preerupted teeth.

A critique of recent economic evaluations of community water fluoridation

Lee Ko¹, Kathleen M. Thiessen²

¹Oakland, CA, USA, ²Oak Ridge Center for Risk Analysis, Oak Ridge, TN, USA

Background: Although community water fluoridation (CWF) results in a range of potential contaminant exposures, little attention has been given to many of the possible impacts. A central argument for CWF is its cost-effectiveness. The U.S. Government states that \$1 spent on CWF saves \$38 in dental treatment costs.

Objective: To examine the reported cost-effectiveness of CWF.

Methods: Methods and underlying data from the primary U.S. economic evaluation of CWF are analyzed and corrected calculations are described. Other recent economic evaluations are also examined.

Results: Recent economic evaluations of CWF contain defective estimations of both costs and benefits. Incorrect handling of dental treatment costs and flawed estimates of effectiveness lead to overestimated benefits. The real-world costs to water treatment plants and communities are not reflected.

Conclusions: Minimal correction reduced the savings to \$3 per person per year (PPPY) for a best-case scenario, but this savings is eliminated by the estimated cost of treating dental fluorosis.

Keywords: Water fluoridation, Economic evaluation, Cost of water fluoridation, Caries prevention, Cost benefit, Cost effectiveness, Effectiveness in adults, Dental fluorosis

Introduction

The USA and several other countries practice community water fluoridation (CWF), which has been promoted as the preferred solution to reduce caries for over half a century.¹ Approximately two-thirds of the U.S. population is treated in this manner according to the Centers for Disease Control and Prevention (CDC).² Community water fluoridation programs have increased water fluoride concentrations to 0.7–1.2 mg/l [0.7–1.2 parts per million (ppm)], although a 2011 proposed recommendation, if finalized, would decrease this to 0.7 mg/l.³

Community water fluoridation is a unique delivery mode of public health care in that fluoride is administered to everyone who drinks the water, regardless of dental status or needs, and at an amount proportional to the water consumed from the fluoridated source, which can range from zero to several liters per day.⁴ At the same time, because most community water is not consumed by people, CWF results in dispersion of a regulated contaminant, fluoride, to the greater environment via wastewater treatment plants, storm sewer systems, and use on lawns and gardens. Fluoridation chemicals typically contain other regulated contaminants (e.g. arsenic),

extending the possibility of human exposures and environmental dispersal.^{5–8}

A central argument for using CWF to reduce tooth decay is the cost savings claimed by the CDC:⁹ Every \$1 invested in this preventive measure yields approximately \$38 savings in dental treatment costs. This argument is repeated by the majority of state governments (Appendix 1) and is frequently cited by proponents to argue for initiating or maintaining CWF.

All \$ signs in this paper refer to US\$ unless otherwise indicated. However, statements such as \$1 saves \$38 are currency neutral.

The CDC's estimate is calculated from the per person per year (PPPY) savings reported by Griffin *et al.*¹⁰ With base-case assumptions, the annual per person cost savings resulting from fluoridation ranged from \$15.95 in very small communities to \$18.62 in large communities.¹⁰ⁱ Table 1 summarizes Griffin *et al.*'s results by population size. The CDC derived the \$1-saves-\$38 claim by scaling the \$0.50 cost and the \$18.62 savings estimate for large systems (>20,000 people) to get \$0.50 : \$18.62 ≈ \$1 : \$38. However, this derivation is not valid because it implies

Correspondence to: Kathleen M. Thiessen, Oak Ridge Center for Risk Analysis, 102 Donner Drive, Oak Ridge, TN 37830, USA. Email: kmt@orrisk.com

ⁱ CDC focused on the smallest and largest systems:⁹ for a population <5,000 people, the net savings is \$19.12 – \$3.17 = \$15.95; for a population >20,000 people, the net savings is \$19.12 – \$0.50 = \$18.62.

Table 1 Estimated costs and savings of community water fluoridation (CWF) for communities of various sizes from Griffin *et al.*¹⁰

Population size	Estimated cost* (\$, PPPY) [‡]	Estimated savings** (\$, PPPY) [‡]
<5,000	3.17	15.95
5,000–9,999	1.64	17.48
10,000–20,000	1.06	18.06
>20,000	0.50	18.62

*Based on a 4% discount rate.

†Calculated with the base-case gross savings of \$19.12.

‡Per person per year.

Table 2 Stated assumptions of Griffin *et al.*¹⁰ and key inputs of the calculation of benefits

Stated assumptions	Key inputs
(1) The benefit is decay prevented and begins at age 6 years	(a) Benefit is the number of decayed tooth surfaces that would otherwise have been treated
(2) The benefit is constant over time	(b) Benefit in dollar amounts, or gross savings, is quantified in terms of averted dental fees for amalgam fillings and averted productivity losses due to a visit to a restorative dentist
(3) All decay is eventually treated	(c) Every decayed surface results in a 1-hour dental visit for a single-surface restoration in the same year it occurs
(4) The adverse effects are negligible	(d) The dental fee for a single-surface filling is \$54, and the productivity loss from the visit is \$18 (the U.S. average hourly wage)
(5) Dental fees equal the cost of dental resources	(e) A single-surface filling is replaced every 12 years with another single-surface filling, up to age 65 years
(6) A decayed tooth surface will always receive a one-surface restoration	(f) It takes one year of exposure for CWF to begin to prevent tooth decay
	(g) CWF averts 0.19 decayed tooth surfaces per person per year (PPPY) on average
	(h) The same rate of caries aversion applies from age 6 to 64 years

CWF: community water fluoridation.

scalability where scalability does not apply: spending more on CWF does not increase caries aversion or caries to be averted.

Griffin *et al.*¹⁰ is the prime example of a body of work that attempts to evaluate the economics of CWF. As the most comprehensive and most cited work, it will be our focus. We limit our analysis to the smallest and largest systems in keeping with the CDC's report.⁹ We also examined and comment on additional CWF cost-benefit analyses (Appendix 2).ⁱⁱ

Key steps in Griffin *et al.*¹⁰

A 1989 workshop¹² at the University of Michigan discussed the cost-effectiveness of CWF and other caries prevention programs, with cost estimates based primarily on data from Garcia.¹³ A 1992 paper by Ringelberg *et al.*¹⁴ improved upon Garcia's cost estimates, and Griffin *et al.*¹⁰ produced their cost estimates (Table 1) by applying minor adjustments to the results of Ringelberg *et al.*,¹⁴ as described later in this paper.

Griffin *et al.*¹⁰ adopted a “societal perspective” and defined benefit as the cost of averted dental fees and associated productivity losses. They used a 4%

discount rate for the main result of \$19.12 gross savings. Griffin *et al.*'s stated assumptions and key intermediate results, organized into a set of key inputs, are provided in Table 2. Note that Input (c) differs from Assumption (3) in the timing of treatment — the authors' calculation was consistent with treatment in the same year. The following steps explain how Griffin *et al.* obtained their value:

Step 1: From Input (d), restoring one decayed tooth surface costs \$54 + \$18 = \$72.

Step 2: As described by Input (e) the lifetime costs of a decayed surface include future replacement fillings; the number of replacements depends on when the decay occurs. Future replacement costs are discounted to arrive at a present value. The first avertable filling is discounted 1 year because of Input (f) in Table 2; replacements take place every 12 years up to age 65 years, based on Input (e).ⁱⁱⁱ For example, for a child age 12.5 years, the lifetime cost at a 4% discount rate was estimated to be \$159.61 as shown in the following equation:

ⁱⁱⁱ While cutting off replacement at age 65 years may appear to underestimate the benefit (cost of fillings), Griffin *et al.* appear to have overestimated by incorrectly or inconsistently applying the factors in the numerator, e.g. the expected lifetime costs of a decayed surface for age groups 55–59 and 60–64 years are both \$69.23 = \$72/1.04 (Table 3), without the factor (which should be around 0.79) to account for fewer teeth at older ages. (Since Griffin *et al.* did not present these factors, except for the few that appear in the Equation (1) example, we are not able to recalculate and correct the numbers in Table 3.)

ⁱⁱ These papers are technically cost-benefit analyses,¹¹ although the term cost-effectiveness is frequently used to refer to the degree that the value of benefit exceeds cost.

$$\$72 \left(\frac{1}{1.04} + \frac{1}{1.04^{13}} + \frac{0.90}{1.04^{25}} + \frac{0.86}{1.04^{37}} + \frac{0.79}{1.04^{49}} \right) = \$159.61 \quad (1)$$

Thus the last replacement takes place at age $12.5 + 1 + (4 \times 12) = 61.5$ in this example. The cost for each filling or replacement filling is adjusted by a factor (the numerator of the term) representing the probability that the tooth remains at the replacement age.

- Step 3: Calculate the national average, using the population distribution in Table 3. Use the midpoint to represent the group in each bracket, e.g. Equation (1) gives the lifetime benefit of an averted decay surface for the 6–19 age group, based on the midpoint, age 12.5 years.
- Step 4: The calculation is repeated for each age bracket, except the first and the last age brackets as described by Input (h) in Table 2. Summing the weighted costs gives \$100.62 as the national average lifetime cost averted per decayed surface.
- Step 5: As CWF averts 0.19 decayed surfaces PPPY, as described by Input (g), the benefit of CWF is thus

$$\text{Gross saving} = \$100.62 \times 0.19 = \$19.12 \text{ PPPY}$$

Costs

Griffin *et al.*¹⁰ based their cost estimates for CWF on Ringelberg *et al.*,¹⁴ except that the numbers were adjusted to 1995 dollars, and a different grouping of community sizes was used. Griffin *et al.* devote one paragraph to their cost estimates.¹⁰

Ringelberg *et al.*¹⁴

Ringelberg *et al.* used data for 44 Florida communities to estimate CWF costs. (Florida's phosphate industry is the largest U.S. producer of fluoridation chemicals.)^{15,16} Ringelberg *et al.*'s improved estimates included costs for bulk storage and containment, labor, and opportunity costs of capital investment, and were based on a larger number of communities than previous estimates.¹³ The estimated average cost increased from \$0.49 PPPY¹³ to \$1.25 PPPY.¹⁴ With phrases such as “allowable initial one-time costs ... were documented by copies of actual invoices for equipment and services”

Ringelberg *et al.*¹⁴ appears detailed and based on actual data. However, these invoices were obtained from the Florida public health dental program, which has the authority to approve costs for communities seeking state grants to implement CWF,¹⁷ and thus reflect costs allowed by the state dental program rather than actual costs.

Ringelberg *et al.*¹⁴ used a 15-year life, with no remaining value, for initial implementation costs, and used 2.4% of the initial costs to calculate the maintenance and repair costs. Labor costs provided by CDC's fluoridation engineer were based on 1 hour per day for all systems and rates of \$7 per hour for small systems and \$9 per hour for medium and large systems. (Note that, in contrast, Input (d) in Table 2 uses \$18 per hour to calculate CWF benefit.) We will show that this is a simplistic and unrealistic view of what is involved in CWF operations.

Reality on the ground

In 2010, amid a budget crisis, the City of Sacramento, CA, instructed all departments to review programs and services. Mr. Marty Hanneman, then Director of the Department of Utilities, wrote in a memo to the City Council:¹⁸

The City of Sacramento has been fluoridating its water supplies just over 10 years. Within that time, the actual cost of operating and maintaining the fluoridation systems has proven to be considerably more than the initial estimate. ... The fluoridation infrastructure at the E.A. Fairbairn Water Treatment Plant is overdue for replacement and will be very expensive to replace. ... Fluoridating water is a very costly and labor intensive process and requires constant monitoring of fluoride concentrations to ensure proper dosages. ... The chemical is very corrosive, so all equipment that is used in the fluoridation process has a very short life expectancy and needs to be replaced frequently. ... but also causes frequent and complex system failures.

This was echoed by Mr. René Fonseca of Carroll-Boone Water District in Eureka Springs, AR, which was required by a 2011 State mandate to begin CWF (Fonseca, 2012, private communication):

Table 3 Griffin *et al.*¹⁰ weighted per person discounted lifetime cost of carious surface initially occurring at various ages

Age (years)	Discounted expected lifetime cost of decayed surface (\$)	1996 U.S. population (%)	Weighted cost (\$)
0–5		8.4	
6–19	159.61	20.4	32.56
20–24	146.95	6.8	9.99
25–29	144.86	7.2	10.43
30–34	128.24	8.3	10.64
35–39	127.76	8.5	10.86
40–44	105.12	7.7	8.09
45–49	105.55	6.6	6.97
50–54	106.42	5.2	5.53
55–59	69.23	4.2	2.91
60–64	69.23	3.8	2.63
65+		12.8	
Total		100	100.62

All of our chemical feed systems require regular maintenance which is routine but fluoride feed equipment often requires replacement and more frequent attention. ... I have toured plants and seen in trade publications deteriorating pipes, steel doors and casing, electrical components, etc. There are millions of dollars spent yearly on infrastructure damage caused by fluoride in our industry.

The realities expressed in these two quotes are not the exceptions. A water plant manager in Alberta, Canada, complained that the fumes from the acid etched the glass, paint, and computer screens of the water treatment plant.¹⁹ Seven years after CWF began in 2001, Riverton, Utah, spent nearly \$1.2 million for two new buildings “to get fluoride out of electrical and pump area.”²⁰

Several incidents of fluoride overfeeds at water-treatment plants have been investigated. Gessner *et al.*²¹ described an accident that occurred in Hooper Bay, Alaska, in 1992, in which 296 residents suffered acute poisoning and a 41-year-old man died. Petersen *et al.*²² reported on an overfeed incident in a residential Connecticut community in 1986. The fluoride caused gastroenteritis in 33% of those who drank the water and itching and skin rashes in those with dermal contact; the acidity leached copper from domestic plumbing. Penman *et al.*²³ investigated an outbreak of acute poisoning caused by a fluoride overfeed in a small rural community in Mississippi in 1993. Several people became ill and connected the onset of their illness to drinking tap water at the same restaurant. A community survey was performed, and the authors concluded that approximately one third of households in the town may have been affected, though the extent remains unknown.

Akiniwa²⁴ examined seven events of acute fluoride poisoning related to the fluoridation of drinking water that have been reported in the U.S. He estimated from these reports that acute fluoride poisonings have occurred at doses of 0.1–0.8 mg fluoride per kg of body weight. One fatal fluoride intoxication caused serious illness in 12 patients, 3 of whom died, in a hospital hemodialysis unit in Chicago in 1993.²⁵ Caused by failure of a widely used deionization system, this event would not have been catastrophic had the water not been fluoridated.

Other incidents reported in local media have included injuries to water plant workers, massive evacuation around an interstate highway, damages to water pipes or concrete floors, and environmental hazards to fish and ground. A number of these incidents are cited in Appendix 3.

An economic evaluation taking a societal perspective should have considered the societal costs from these inevitable consequences of CWF. However, comprehensive data needed to estimate such costs

are lacking, because the government agencies that should track these incidents appear to have a conflict of interest in protecting and defending the CWF policy (e.g. Florida;²⁶ Layton;^{27iv} Appendix 1). Nevertheless, evidence presented here demonstrates that Ringelberg *et al.*¹⁴ were unrealistic even considering only the direct costs of CWF to a water system.

Real-world estimates

In late 2010, Black and Veatch Corporation (Overland Park, KS USA) was retained through a competitive bid process to perform an objective evaluation of the fluoride program of the city of Sacramento, CA. After a comprehensive and detailed review, the study²⁸ observed that immediate and future upgrades would be needed to continue fluoridating and to achieve modest operational efficiency improvements. Noting that Sacramento's operational costs were within industry practice, the report developed detailed cost estimates and gave a different picture from Ringelberg *et al.*,¹⁴ e.g. the labor cost was set at a rate of \$100 per hour, in contrast to the \$7/\$9 per hour labor rate from the CDC. The city's engineer, Mr. Brett Ewart, explained (Ewart, 2012, private communication):

The 100/hr. is a hybrid rate used to represent the large variety of machinists, electrical staff, water quality staff, management, etc., that work on the program. The amount of staff time (and type of staff) dedicated to the fluoride program is flexible. Some maintenance activities are generally fixed, others are reactionary and difficult to predict in advance. The rate would include the employees' salary, benefits, and overhead to perform the work.

Sacramento's water system consisted of the following: One large treatment plant supplying 44% of the water, whose fluoridation system had already been updated in 2007; a second large treatment plant (Fairbairn WTP) supplying 42% of the water, whose fluoridation system was in need of replacement; and 27 wells supplying 14% of the water, and whose fluoridation systems also required updates.²⁹ The overall cost estimates provided by Black and Veatch for the needed replacement and updates, annualized using a 2.5% discount rate over a 20-year planning horizon,^v were \$1 million for the 27 wells and \$464,000 for the Fairbairn WTP.²⁹ The cost projection for the Fairbairn WTP is applicable for large water treatment plants, while the cost projections for the well upgrades are applicable for small systems.

^{iv} In a letter to Davis County Health Department and others, the Mayor of Layton, Utah strongly protested that the costs of fluoridation to the citizens of Layton and Davis County were far greater than the costs portrayed by the Department when it “clearly knew better”.²⁷

^v First 5 Sacramento, the organization that funded the study, may fund the capital update cost with a condition that requires the city to commit to CWF for 20 years, regardless of the city's future fiscal conditions.¹⁸ In July 2012, the city accepted a grant from First 5 Sacramento to continue fluoridation until June 30, 2015, even though the grant will provide less than 10% of the system costs over the next 3 years.³⁰

Table 4 Examples of fluoridation cost estimates

Water districts	Year Est	Pop (in thousands)	Reported implementation (I) and annual operation and maintenance (O) costs	PPPY (\$) 15 years, 4% (I)
Napa, CA ³⁴	2003	77	I: \$1M; O: \$150,000	3.07
New York, NY ³⁵	2008	8,350	I: \$12.57M (2 plants); O: \$11.14M (chemicals)	1.45
San Jose, CA ³⁶	2011	1,000	I: \$23M; O: \$1.732M (Wells only)	3.72
Watsonville, CA ³²	2011	51	I: \$50/person; O: \$4/person	8.33
Portland, OR ³⁷	2012	900	I: \$3.5M–\$7.6M, O: \$575,000	0.98–1.37
Carroll-Boone, AR ^{33,38}	2012	25	I: \$894,000–\$1.23M	3.09–4.26†
Davis, CA ³⁹	2013	67	I: \$1.1M–\$2.4M; O: \$228,800–\$240,700	4.84–6.69
Riverton, UT ²⁰	2000	35	I: \$90,000 (estimate)	0.22†
	2001		I: \$200,000 (actual)	0.49†
	2008		I: \$1,174,278 (actual w/2 new buildings)	2.90†
Jordan Valley, UT ⁴⁰	2000	82	I: \$56,000–\$2.1M (estimates)	0.06–2.22†
	2004		I: \$2.45M; O: \$297,000 (actual)	6.21

†Estimates do not include operation and maintenance costs.

To calculate the PPPY costs, we allocated the total population of Sacramento, 466,000 people (2010 U.S. Census), to the 27 wells and to the Fairbairn WTP using the percentages of total water supplied of 14% and 42%, respectively. The allocated populations are 65,000 and 196,000, respectively. Dividing the total costs by population and number of injection sites, we obtain a cost estimate of \$15.38 and \$2.37 PPPY for a single-injection point water system serving 2,400 and 196,000 people, respectively. (Systems serving 2,400 people are not rare. Of the 44 systems in Ringelberg *et al.*¹⁴ three systems had smaller populations and seven systems had smaller populations per injection site.)

We considered whether to adjust for the cost of living in Sacramento and determined that there was no need. The cost of living for Sacramento is 8% higher than the U.S. average.³¹ This differential, however, is easily offset by other considerations, e.g. the use of a 2.5% instead of 4% discount rate. The cost projection also assumes that the Health Department continues to waive a requirement for certain standard equipment. In addition, actual bids for construction may turn out to be much higher than the engineer's estimates.^{32,33} Finally, it was unknown whether implementing the recommendations would solve the city's fluoridation issues.²⁹

A small water system serving more than 2,400 people is expected to cost less than \$15.38 PPPY. Similarly, many large systems serve less than 196,000 people and are expected to cost more than \$2.37 PPPY. (Note that large water districts serving more than 196,000 people will not necessarily cost much less than \$2.37 PPPY, because such water districts often have multiple treatment plants and/or auxiliary wells, which make them equivalent to a smaller single-injection point system). Therefore, reasonable cost estimates for the smallest (<5,000 people) and largest (>20,000) systems in Table 1 would be about \$10 and \$3 PPPY, respectively.

Strictly speaking the annual cost projections provided by Black and Veatch are 20-year financing costs.

At the end of the 20-year period, components such as new buildings may still have value. However, given the ability of the chemicals to degrade concrete (Appendix 3 items 17 and 19), significant annual maintenance and repair costs after the financing period are expected. In addition, circumstances could require a water system to implement major infrastructure changes to their fluoridation facilities. Sacramento is such an example. Despite implementing fluoridation comparatively late (around 2000), the city has already endured major infrastructure adjustments and is considering more, long before the 20-years projection period. Finally, it is possible that a system may discontinue CWF; in that case, buildings constructed specifically for CWF may hold little value.

Other estimates

The Black and Veatch report cited above is valuable in that it is recent, comprehensive, detailed, and authored by a firm that has consulted on other fluoridation programs. In general, reliable cost information for CWF programs is difficult to obtain, and information provided in response to a request is often limited to the cost of the fluoride chemicals. In Table 4, we present additional cost information and estimates collected from various sources.^{20,32–40} The majority of these are cost estimates prior to implementation; New York and some Utah figures show actual costs. Costs are reported either for implementation (*I*) or for annual operation and maintenance (*O*). For convenience, we calculate a PPPY cost by annualizing the implementation cost (*I*) using a 4% discount rate over 15 years^{vi} (meaning \$100 annualizes to \$8.65) and normalizing the total, i.e., dividing the annualized *I* plus *O*, if available, by

^{vi} The service life of fluoridation equipment depends very much on the component and on the service conditions. According to Black and Veatch,²⁹ only a few components in indoor setups can expect a service life of 15 years or more, and some components have a service life of only 5–10 years in an outdoor setup.

population. (Population figures are taken from the CDC website or the U.S. Census Bureau if they are not reported in the source article.)

Many of the cost estimates shown in Table 4 are incomplete or partial, or the values are underestimated. Several (denoted with †) do not include operation and maintenance (O&M) costs. The New York numbers consist of costs to rehabilitate CWF facilities in two plants, and only chemicals are included in O&M. The San Jose numbers provided in a Black and Veatch study were for wells that provide only half of the water for the city, which imports the other half. The preliminary estimates for Napa, CA are from about the time that Sacramento began its fluoridation program and probably suffer from similar underestimates of costs.¹⁸ The estimates for Portland, OR were provided by the Water Bureau after a meeting with representatives from the CDC and the organizations pushing to fluoridate the city. The \$575,000 O&M figure appears unrealistic — Sacramento already paid over \$400,000 back in fiscal year 2008/2009 for hydrofluorosilicic acid (HFSA) to fluoridate 86% of their water; this translates to about \$1 PPPY for the cost of HFSA alone. In addition, the O&M estimate excluded costs of additional caustic or other corrosion control chemicals to bring the pH back to an appropriate level, and the cost of additional capital improvements needed to mitigate water quality impacts were not included in the estimated capital costs.³⁷

Community water fluoridation proponents have a poor track record for cost estimates. For example, the county health board of Davis County, UT, provided a cost estimate of \$1.38–\$2 PPPY prior to a vote in 2000, but the true implementation cost was \$4.29 PPPY.⁴¹ This is also seen in the estimates/observed figures for the two Utah systems in Table 4. In 2001, Arkansas state legislators passed a state mandate to fluoridate community drinking water. They were partially motivated by an offer from Delta Dental of Arkansas to donate \$500,000 total toward startup costs for the 32 water systems affected.⁴² Later Delta Dental pledged \$2 million for 34 systems and soon found itself needing to raise another \$6–\$10 million.⁴³ (State mandates in California and Arkansas both require the initial implementation costs be funded by outside sources.)

Overall, reported costs of CWF are consistent with our real-world estimates and not with those estimates^{10,14} commonly cited by fluoridation proponents.

Costs of dental fluorosis

Griffin *et al.*'s Assumption (4) in Table 2, that the adverse effects of CWF are negligible,¹⁰ is common to most cost-benefit analyses of CWF. It is inexplicable that neither Griffin *et al.*¹⁰ nor other similar studies

(Appendix 2) mention dental fluorosis, defective enamel in permanent teeth due to childhood over-exposure to fluoride.^{44,45} Community water fluoridation, in the absence of other fluoride sources, was expected to result in a prevalence of mild-to-very-mild (cosmetic) dental fluorosis in about 10% of the population and almost no cases of moderate or severe dental fluorosis.⁴⁶ However, in the 1999–2004 NHANES survey, 41% of U.S. children ages 12–15 years were found to have dental fluorosis, including 3.6% with moderate or severe fluorosis.⁴⁷

As an increased prevalence of dental fluorosis became evident, there were attempts to shift attention to other sources of swallowed fluoride, such as toothpaste.⁴⁸ However, 1/4 liter (or about 8 oz) of fluoridated water at the “optimal” concentration of 1 mg/l contains the same amount of fluoride as a bead of toothpaste (0.15% w/v fluoride ion) 0.68 cm in diameter. Regarding other sources of ingested fluoride, Szpunar and Burt⁴⁹ state that the factor that differentiates the studied communities with respect to the prevalence of caries and fluorosis is the fluoride concentration in the community water supply.

Dental fluorosis had been dismissed as cosmetic by CWF promoters and government agencies in the U.S. until the National Research Council (NRC) concluded that “severe dental fluorosis” qualified as an adverse health effect due to increased risk of caries and loss of dental function.⁴⁴ When an economic evaluation is framed as having a societal perspective, it should include effects that result in social costs, regardless of whether the effects are cosmetic or systemically harmful. In a later paper, Griffin *et al.* indicated that some people may want “esthetic restorative procedures” to treat fluorosis, but treatment costs were not estimated.⁵⁰ We next provide a high level estimate of the minimal costs of treating dental fluorosis.

Dental fluorosis is classified by the severity of the discoloration, the presence of pitting, and the extent of the tooth surfaces affected.^{44,45vii} Although bleaching and microabrasion can be used to improve the appearance of milder cases of fluorosis, moderate and severe dental fluorosis can require extensive treatment to improve the cosmetic appearance and prevent further loss of enamel.^{44,45} Treatment options include applications of veneers or crowns. Porcelain veneers may cost more than composite resin veneers (\$800–\$2,500 vs. \$250–\$1,500), but they require less frequent replacement (10–15 vs. 5–7 years).^{52,53}

vii Dean's classification for very mild, mild, moderate, severe and very severe dental fluorosis: at least two teeth contain mottled surface area covering less than 25%, between 25 and 50%, between 50 and 100%, 100% (with discrete pitting), and 100% (with confluent pitting) of the tooth surface, respectively.⁵¹

Crowns are “usually used as a last resort because they can be a threat to tooth vitality.”⁴⁴

For this analysis, we assume that each moderate or severe fluorosis tooth receives a porcelain veneer treatment. We further assume that a child with the condition gets the first treatment at age 13.5 years, and the veneers are replaced every 12 years. The lifetime cost of a veneer is calculated using equation (1), except the \$72 is replaced by the cost of a veneer, for which we use a lower-end number of \$1,000. This gives a lifetime cost of \$2,217. Dean’s Enamel Fluorosis Index, the most widely used classification of dental fluorosis, is assigned on the basis of the two most-affected teeth.⁴⁴ Thus, the lifetime cost of veneers for a child with moderate or severe fluorosis would be at least \$4,434.

Beltrán-Aguilar *et al.*⁴⁷ reported that 3.6% of U.S. children ages 12–15 years in 1999–2004 had moderate or severe dental fluorosis, but did not provide information on the fluoridation status of the affected children. At most about 60% of the U.S. population received fluoridated water during the time period when these children were susceptible to development of fluorosis.^{viii} Both the prevalence and the severity of dental fluorosis are correlated with the fluoride concentration in drinking water.^{45,49,55} If all of the cases of moderate and severe dental fluorosis occurred in fluoridated rather than nonfluoridated areas, then at least 6% of children in fluoridated areas would have moderate or severe fluorosis.^{ix} For our calculations, we have assumed that 5% of children in fluoridated areas have moderate or severe fluorosis. From Table 3, the percentage of children at age 13.5 years is about 20.4%/14 = 1.46%. Thus the minimum cost of treating dental fluorosis is estimated to be $\$4,434 \times 1.46\% \times 5\% = \3.24 PPPY.

Other costs

There are other costs missing from the conventional cost-benefit analyses of CWF (Appendix 2). The NRC’s 2006 report on fluoride exposures and toxicity found that the U.S. Environmental Protection Agency’s (EPA) drinking water standard for fluoride was not protective of human health.⁴⁴ The NRC did not evaluate CWF for safety or efficacy, but the report showed that the average fluoride exposures associated with adverse health effects are within the expected range of fluoride intake for populations with fluoridated water, especially for infants, young

children, and people with high water intake.^{44,56x} Peckham and Awofeso’s recent review specifically concluded that fluoridation has “significant costs” in relation to adverse effects on human health, although these costs were not quantified.⁵⁷

Health risks to water plant operators are not included in most discussions of CWF, but these individuals may receive substantial occupational exposures to fluoride if the safety infrastructure or training is not adequate or if equipment malfunctions.^{58,59}

Most of the fluoridation chemicals used in the U.S. are byproducts of the phosphate fertilizer industry in North America or Asia.^{15,16,60} Since only a small percentage of municipal water is actually consumed by people, the practice results in wide dispersion of a regulated pollutant into the environment via local water districts. Fluoride pollution may result in serious ecological risks to aquatic organisms.⁶¹

Fluoride is regulated by the U.S. EPA as a contaminant in drinking water⁶² and as an air pollutant.⁶³ A number of fluoride compounds are considered hazardous substances with assigned Reportable Quantities.⁶⁴ In addition, fluoridation chemicals often contain other regulated contaminants.^{5–8} Hirzy *et al.*⁶⁵ estimated that the typical concentration of arsenic in the major fluoridation chemical (HFSA) could be responsible for several excess lung and bladder cancers per year in the U.S. and the consequent costs of treatment.

Political costs have at times been acknowledged but not included in CWF analysis.¹⁰ This category goes beyond costs associated with fluoridation referenda to include government expenditures for promoting fluoridation programs, costs associated with lobbying elected officials on this issue, legal challenges to fluoridation programs, and possible personal injury litigation involving workers or members of the public.^{66–70}

There are also costs associated with avoiding fluoridated tap water, either by need or by choice. These are all societal costs of CWF that should not simply be excluded or assumed negligible without examination.

Benefits

The primary benefit attributed to CWF is prevention of caries, although a major review in the United Kingdom reported no relevant studies of “evidence level A (high quality, bias unlikely)” and expressed surprise that little high quality research had been undertaken.⁷¹ Caries prevention is commonly assessed in terms of a reduction of decayed, missing, or filled

^{viii} Infants and young children are most at risk for exposures leading to dental fluorosis.⁴⁵ Children ages 12–15 years when surveyed between 1999 and 2004 were born between 1984 and 1992. Centers for Disease Control and Prevention’s data indicate that 53–60% of the U.S. population between 1984 and 2002 received fluoridated water.⁵⁴

^{ix} $3.6 / 53\% = 6.8\%$ and $3.6 / 60\% = 6\%$.

^x People with high water intake include athletes, outdoor workers, military personnel, and people with medical conditions such as diabetes insipidus or diabetes mellitus.⁴⁴ People with impaired kidney function may have high water intake and might also have reduced urinary excretion of fluoride.⁴⁴

teeth (DMFT), DMF tooth surfaces (DMFS), or their variations.^{xi} Estimation of averted caries is obviously central to a cost-benefit analysis.

Griffin *et al.*¹⁰ relied on the theory that caries averted by CWF can be considered in terms of two factors as shown in the following equation

$$\text{Averted caries} = \text{Incidence} \times \text{Effectiveness} \quad (2)$$

where Incidence is the per person annual caries increment without CWF, and Effectiveness is the percentage reduction in caries due to CWF.

Before we explain and critique how Griffin *et al.*¹⁰ derived their values for Incidence and Effectiveness, it is worthwhile to examine the concepts of incidence and effectiveness in the context of CWF.

Incidence

Griffin *et al.*¹⁰ treat the reported caries incidence in selected nonfluoridated areas as the caries incidence in the absence of CWF. However, they have not accounted for the decline in caries rates over time apart from CWF or the variability in caries rates among various areas, independent of CWF.

It has been known for decades that tooth decay prevalence has been declining in developed countries regardless of CWF status, i.e., the “secular decline”.¹¹ Diesendorf⁷² listed over 20 studies which reported substantial temporal reductions in caries in unfluoridated areas. In many cases, the magnitudes of the reduction were comparable to those attributed to fluoridation in some fluoridated areas; it was also pointed out that fluoride toothpaste or supplement could not have accounted for many of the reductions.

That fluoride is not needed for dental health is not surprising. A 1952 NRC report⁷³ described studies reporting that the teeth of ancient peoples and modern primitive peoples were relatively free from dental caries, in a striking contrast to the teeth of modern people. However, primitive peoples had increased rates of caries when brought into contact with a modern diet. This is consistent with the fact that caries are rare in animals in the wild. Finn⁷³ also described the significant geographic and temporal variability of caries prevalence, citing Hagan⁷⁴ for demonstrating how caries prevalence may vary within narrow geographic limits, as well as fluctuating within the same area from time to time.

Hagan⁷⁴ studied 12 communities in Georgia, including 24,092 children, and reported the following by community: The average annual caries increments were 0.18–0.90 for children up to 16 years old; the

DMFT ranged from 0.40–2.44 at age 7 years to 1.41–10.64 at age 16 years; the percentage of children with at least 1 DMFT ranged from 23–77% at age 7 years to 58–100% at age 16 years. The ranges of DMFT for a given age in these pre-CWF situations approach or exceed the differences reported between fluoridated and nonfluoridated locations in more recent years. For example, Heller *et al.*⁵⁵ reported mean DMFS values ranging from 2.53 (0.7–1.2 ppm F) to 3.08 (<0.3 ppm F), with a mean DMFS of 2.75 for the entire sample (18,755 U.S. schoolchildren ages 5–17 years with a history of a single residence). The percentage of caries-free children ranged from 52.5% (>1.2 ppm F) to 57.1% (0.3–0.7 ppm F), averaging 54.6% for the entire sample. McDonagh *et al.*⁷¹ reported that, among 15 studies analyzed, the mean differences in dmft or DMFT ranged from 0.5 to 4.4 (median 2.25).

Other historical data contradicting the idea that fluoride is needed for dental health have been reported. Using data from New Zealand Health Department records of 5-year-olds’ tooth decay from 1930 to 1990, fluoridation coverage, and fluoride toothpaste sales, Colquhoun⁷⁵ showed that the dramatic decline in tooth decay started long before water fluoridation, fluoride toothpaste, or application of fluoride. Another paper noted that the DMF rate in children ages 12–15 years in Taiwan was as low as 1/3 to 1/6 of that in children of the Western countries where water fluoridation had been in effect for 8–11 years.⁷⁶

Studies that attributed differences in tooth decay rates between selected communities to CWF may have only observed these geographic or temporal variabilities, independent of any effect of CWF. Other studies (see Appendix 5) found that non-fluoridated cities also experienced rapid reductions in tooth decay rates without installing CWF, even though these cities had previously been compared with fluoridated cities as evidence that CWF reduces caries. Hence the concept of a no-fluoridation caries incidence rate has little meaning.

Effectiveness

Griffin *et al.*¹⁰ derived their estimate of effectiveness from Brunelle and Carlos,⁷⁷ who reported on the second of two large-scale National Institute of Dental Research (NIDR) surveys, completed in 1980 and in 1987, respectively. Each survey sampled and examined approximately 40,000 U.S. school children aged 5–17 years.

Community water fluoridation effectiveness has been variously reported in the literature. The unit of measure can be variations of DMFT, DMFS for permanent teeth, the corresponding measures for deciduous teeth, or the percentage of children with no caries. They could be for a single age or for an age range. Information about length of exposure to CWF

^{xi} DMFS counts the number of decayed (untreated), missing, filled tooth surfaces and DMFT counts teeth instead of surfaces. (An adult without wisdom teeth has 28 permanent teeth and 128 tooth surfaces.) Capital letters refer to permanent teeth and lower case letters (dmfs, dmft) to deciduous teeth.

may or may not be included. Study parameters are often poorly defined and confounding factors not typically examined.

Often a percentage value is produced from some relative differentials and referred to as CWF effectiveness, despite that the percentages come from different situations. Some may argue that since all the different kinds of studies point to similar ranges of effectiveness, it is proof that the effectiveness estimates are robust. However, the premise of this argument is false.

First: Units. Units of measures do affect the results. An independent investigation of the 1987 NIDR data using DMFT instead of DMFS led to the conclusion of no effectiveness.⁷⁸ When asked about results for teeth, Brunelle was quoted to have said that they “are in a box somewhere” and she “could not remember what exactly the results were” and that the decay rate for teeth “is rather low so that there is very little difference in most anything.”⁷⁹ Truman *et al.*⁸⁰ estimated effectiveness in units of teeth from data reported in a number of studies (Table 5) even if a study reported data in both teeth and surfaces.

Studies reporting results in teeth were more common in the past. The focus shifted toward surfaces as the prevalence of caries dropped and caries became concentrated in a small subset of the population.⁸¹ Measuring caries in units of surfaces gives heavy weight to the small percentage of people with high levels of decay.^{xii}

Second: Lengths of exposure. There are two relevant exposures: exposure to carious influence and exposure to CWF.

Exposure to caries is determined in part by the time a tooth erupts. Usually age is used as a surrogate for the length of this exposure. If a study examines subjects of a range of ages and one effectiveness number is to be presented, which age is selected or how different age groups are weighted to calculate an average can produce different results. Appendix 4 provides examples of studies showing differences in caries experience that were attributed to CWF exposures, when the results may be better explained by differences in age distributions of the populations being compared.

Exposure to CWF is often handled by comparing only those with lifetime exposure to those with no exposure. However, if a result is contingent on excluding partial exposure it weakens the argument for CWF as a public policy. More importantly, this approach introduces a probable bias if the two exposures (to caries and to CWF) are not independent.

Evidence indicates that ingested fluoride may delay tooth eruption,^{44,45,85} which would affect caries scoring by giving the appearance of less decay for a given age.^{44,45} Komárek *et al.*⁸⁶ used data for actual tooth eruption time and found no convincing effect of fluoride intake on caries development. Weaver⁸⁷ indicated that “the caries inhibitory property of fluorine seems to be of rather short duration,” consistent with a delay in the exposure of permanent teeth to a cariogenic environment.

Third: Methods. The methods of determining an effectiveness value are even more problematic, especially in regard to policy references. This is best demonstrated by an examination of Truman *et al.*,⁸⁰ which was co-authored by Griffin, other CDC personnel, and a Task Force appointed by the Director of the CDC. The Task Force was established by the U.S. Department of Health and Human Services (HHS) in 1996 to provide recommendations for community preventive services, programs, and policies. Reported in 2000, the findings of the Task Force’s systematic review⁸⁸ became the main results of Truman *et al.*⁸⁰ on CWF effectiveness, as well as the basis for Healthy People^{xiii}2010’s goal of increasing CWF in the U.S. to cover 75% of the population.⁹¹ Healthy People 2020⁹² continues with a goal of increasing coverage to 79.6%.

Truman *et al.*⁸⁰ based their conclusion on 14 studies in three groups (Table 5):^{76,93–105}

- Studies starting or continuing CWF with before and after measurements (Group A-On)
- Studies stopping CWF with before and after measurements (Group A-Off)
- Studies starting or continuing CWF with only post measurements (Group B-On)

They calculated a number of “estimates of effectiveness” from the studies using two formulas, one for Group A (before-and-after) and one for Group B (post measurements only). The measures were mostly DMFT or dft.

The median of estimates was taken to represent the CWF effectiveness for each study type; the results were 29.1% for Group A-On, 50.7% for Group B-On, and 17.9% for Group A-Off. (The 29.1% and 50.7% figures were presented by the Task Force.)⁸⁸ With these numbers the authors concluded “strong evidence shows that CWF is effective.” This conclusion is not valid. We describe three areas of problems below (details provided in Appendix 5).

^{xii} Proponents often appeal to sympathy for young children with high levels of tooth decay to argue for CWF.⁸² However, early childhood caries (ECC) is not prevented by fluoride.^{83,84}

^{xiii} CDC’s “Healthy People” series “provides science-based, national goals and objectives with 10-year targets designed to guide national health promotion and disease prevention efforts to improve the health of all people in the United States.”⁸⁹ One goal of Healthy People 2000, 2010, and 2020 has been to “increase the proportion of the U.S. population served by community water systems with optimally fluoridated water.”^{90–92}

Selection of studies: Studies of higher quality and relevance such as the NIDR surveys or other U.S. studies were not included. Many studies on the effect of cessation of CWF (Group A-Off) were omitted even though this group had only three studies. Not all included studies are relevant for CWF or meet the stated criteria.

Selection of estimates: The number of estimates selected from each study appears arbitrary. Fewer estimates were selected from large-scale studies reporting findings in detail than from small studies reporting few findings. Sometimes the selected estimate did not fit the group it was placed in. Selection of arbitrary numbers of estimates from an arbitrary set of studies does not lead to confidence in the reported median.

Selection of formula: Within the limited set of studies and estimates selected, the authors failed to apply their formula consistently. In addition, the results from the application of the formula can be misleading. Upon examination of the data, some purported positive outcomes are revealed as purely an artifact of the formula — the never-fluoridated communities had a dramatic reduction in caries without the help of CWF.

The incidence and effectiveness in Griffin et al.¹⁰ Three estimates for Incidence were compiled from several unrelated sources while three estimates for Effectiveness were derived from a single source. They are paired by magnitude and substituted in Equation (2) to arrive at three cases of averted DMFS as shown in Equation (3).

$$\begin{aligned} \text{best case : } 1.16 \times 29\% &= 0.34 \\ \text{base case : } 0.76 \times 25\% &= 0.19 \\ \text{worst case : } 0.33 \times 12\% &= 0.04 \end{aligned} \quad (3)$$

The base-case averted DMFS of 0.19 is the key input (g) in Table 2. (Note that not all studies cited

Rugg-Gunn and Nicholas ¹⁰⁵	5	B-On/3

by the authors measured DMFS, and the differences were not always pointed out.) We next examine how the numbers on the left-hand side were derived.

The Incidence

Griffin et al.¹⁰ obtained three sets of annual caries increments in nonfluoridated communities as Incidence; they are reproduced in Table 6. The sources were, respectively, published studies cited in Garcia,¹³ the National Survey of Oral Health (NSOH) in U.S. Schoolchildren and a separate NSOH in Employed Adults and Seniors, and the First and Third National Health and Nutrition Examination Survey (NHANES I, 1971–1974 and NHANES III, 1989–1994).

For the best case, the authors used the controls in Garcia's review¹³ of published studies of clinical and community trials. For the base case, the incidence for children was imputed by dividing the difference in mean DMFS for 6-year-olds and 17-year-olds living in communities without fluoridation by 11. Unrelated to the children's survey, the adult NSOH survey was measured in DFS (without M, missing surface) and was not stratified by community fluoridation status. Hence, they imputed the incidences by using the least fluoridated region (Pacific). They scaled the mean DFS by the ratio of average numbers of teeth in the two age points to adjust for missing teeth. They also added root caries incidences from other studies. For the worst case, the authors imputed the incidence using data from two NHANES surveys, which did not report fluoridation status. A major difference from the base case was that they tried to use data on the same birth cohort over time. Additional adjustment was applied because earlier NHANES data measured DFT instead of DFS.

The source of the best case, Garcia,¹³ was the basis for discussion of CWF in the 1989 Michigan Workshop. Workshop participants were critical of the numbers. "Most work groups felt that the estimates of caries incidence in Garcia's report were generally too high and reduced them by several decimal points, though some reduced them further."¹² Griffin et al.¹⁰ also stated in their discussion that the samples were probably not representative of the general population. Thus, the best case is invalid.

Griffin et al.¹⁰ also admitted that the base case was overestimated. They remarked that, given the secular decline in caries, using cross-sectional data to impute

Table 6 Griffin et al.'s estimates of annual caries increment (tooth surfaces) from selected studies, by age¹⁰

Source	Age (year)			
	6–17	18–44	45–65	Avg.
Published studies (best case)	1.40	0.83	1.24	1.16
NSOH (base case)	0.77	1.09	0.43	0.76
NHANES (worst case)	0.49	0.49	0.00	0.33

caries increment from the NSOH would overestimate current increment. Secular decline^{11,72} refers to the widespread decline in caries observed in nonfluoridated areas. It means that when a 6-year old living in a nonfluoridated area today grows up to be 17 years old, he will likely have fewer caries than his 17-year old neighbor has today. Thus using the latter to represent the former (cross-sectional data) overstates the incidence of caries.

The Effectiveness

As with the Incidence, Griffin *et al.*¹⁰ presented three cases for Effectiveness, all essentially from Brunelle and Carlos.⁷⁷ The 1987 NIDR Survey examined 39,206 children, of whom about 92% had complete residence histories. Brunelle and Carlos⁷⁷ analyzed data from 16,398 children with either lifelong exposure or no exposure to CWF and presented mean DMFS by age (see Table 12) and by region (Table 7). The national averages from this subset of data showed a difference of 0.6 DMFS, or 18%, between the two exposure groups. By further restricting their sample to a subset of 5,954 children (reportedly by removing all data points with any supplemental fluoride exposure), the 18% difference was raised to 25%. No age or regional distribution was shown for this restricted set of data. Griffin *et al.*¹⁰ took this 25% as the base-case Effectiveness.

Brunelle and Carlos⁷⁷ ignored 58% of the total data (or 55% of those with complete residence histories), despite that partial exposure data from this national survey can be analyzed and are informative.⁷⁸ It is therefore questionable if the 18% reduction in DMFS represents the findings of the survey. Even more troublesome is the 25% adopted as the base-case Effectiveness, as it ignores 85% of the survey data.

The best- and worst-case Effectiveness, 29% and 12%, respectively, were supposed to be calculated from the best three and the worst four effective regions. However, the worst four regions (I, II, III, and V in Table 7) would average closer to 6% than 12% using regional population data found elsewhere.¹⁰⁶ It appears that Griffin *et al.*¹⁰ may have removed Region III (Midwest) from the calculation given the

comment: “The negative effectiveness value in the Midwest may have been due to small sample size because few children living in this region actually received nonfluoridated water.” This criticism would equally apply to the highest-effectiveness Region VII (Pacific), as few children in this region received fluoridated water, but it was not considered a problem.

Lack of evidence for adults

Assumption (2) and Input (h) in Table 2 assume the same CWF benefit to age 64 years, despite that estimates of Effectiveness were derived from a children’s survey. Two adult studies^{51,107} were cited to support this extrapolation. However, the data presented in Grembowski *et al.*¹⁰⁷ do not support its conclusion, and Eklund *et al.*⁵¹ appear to be mis-cited in addition to the fact that the concentrations involved, 3.5 versus 0.7 mg/l, are irrelevant to an evaluation of CWF. We examine each of these studies below.

That few adult studies are available has been noted elsewhere. Garcia¹³ stated that very limited information exists in the literature about caries incidence in adults, and Newbrun¹⁰⁸ identified only seven adult studies; he commented that very few acceptable data exist and that the comparison was either between those living in low-fluoridated and high-fluoridated (greater than optimal) communities or between those living in optimally fluoridated and high-fluoridated communities. Thus, it is not surprising that Truman *et al.*⁸⁰ included “What is the effectiveness of CWF among adults aged ≥ 18 years?” among important unanswered questions.

More recently Slade *et al.*¹⁰⁹ presented an analysis of Australian data from a 2004–2006 survey, and Griffin *et al.*¹¹⁰ did a meta-analysis of several earlier studies. We examine these papers in detail in Appendix 4. Among other problems, both articles (and several studies included in the latter) failed to properly account for different age distributions.

Grembowski *et al.*¹⁰⁷

This study examined Washington state employees and spouse-dependents aged 20–34 years living in Olympia, Seattle, or the Pullman, WA/Moscow,

Table 7 Mean DMFS of each U.S. region by CWF status (1986–1987) from Brunelle and Carlos⁷⁷

Region	Lifelong exposure	No CWF exposure	Population with CWF (%)	Relative Diff (%)
I	3.11	3.45	55	9.9
II	3.08	3.42	49	9.9
III	2.86	2.69	74	–6.3
IV	2.75	3.60	54	23.6

VI	2.36	3.07	34	23.1
VII	1.42	3.61	19	60.7
U.S.	2.79	3.39	53	17.7

DMFS: decayed, missing, or filled tooth surfaces; CWF: community water fluoridation.

Table 8 Average number of decayed and filled surfaces by period of fluoridated exposure in lifetime from Grembowski *et al.*¹⁰⁷

Period of fluoridation exposure in lifetime	No. of adults	Average age	College degree (%) [*]	Average DFS
No exposure in lifetime	226	30.4	35	27.9
Pre-eruptive exposure patterns (ages 0–5 only or ages 0–14 only)	40	30.1	40	20.0
Post-eruption exposure patterns (ages 15–34 only)	266	30.7	78	22.2
Exposed most of life	63	31.0	72	15.7

^{*}Includes those with a college degree and those with graduate work or a graduate degree.

Idaho area. The data presented in this study are reproduced in Table 8.

Griffin *et al.*¹⁰ paraphrased Grembowski *et al.*¹⁰⁷ claiming that the average 30-year-old adult with continuous lifetime exposure to fluoridated water had 8.7 fewer decayed or filled surfaces, or a 31% reduction compared with 30-year-old adults with no CWF exposure. However, based on the data (Table 8), it is unclear how these figures were estimated.

There are additional problems with Grembowski *et al.*¹⁰⁷ For example, it was stated that “1,066 ... formed the data base for this analysis”; but the paper shows results for only 595 participants, and makes no mention of the other 471 participants. In other words, 44% of the data are unaccounted for.

Grembowski *et al.* described calculating the years of fluoridation exposure for the age ranges: 0–5, 6–14, 15–19, and 20–34 years, to “explore systemic and topical effects.” However, Table 8 has a group described as having an exposure pattern, meaning exposure to CWF for the majority of time during the period of “ages 0–5 only or ages 0–14 only” — it appears to be a hastily created grouping to avoid showing results from the original design. Indeed only 40 adults were in this group, so that they had to qualify their conclusion that “exposure to fluoridated water during childhood has lifetime benefits” with “These results are tentative, however, because the pre-eruptive sample size was small.”

The four groups differed in their education levels as well as their fluoride exposure (Table 8), with the no-exposure group having the lowest percentage with a college degree. The CDC has reported that oral health disparities are associated with lower education level.^{111xiv} Although Grembowski *et al.* pointed out the difference in education level, they did not evaluate the possible impact of this difference on their findings.¹⁰⁷

Grembowski *et al.* revealed that people in the nonfluoridated sites had less untreated decay than in the fluoridated sites. They also pointed out that the

filled component of DFS is influenced by dentists’ treatment decisions. They noted that dentists in nonfluoridated areas may restore teeth in adults more frequently, and that use of identical treatment criteria would “slightly reduce” their estimates of fluoridation’s benefits.

They claimed to offer evidence that exposure to fluoridated water during childhood has a lifetime benefit and concluded that their findings provide support for health officials to continue and expand this public health program. Their data do not support the conclusion.

Eklund *et al.*⁵¹

This study examined the communities of Lordsburg and Deming, New Mexico, with fluoride concentrations of 3.5 and 0.7 mg/l in the drinking water supply, respectively. Subjects were approximately 30–60 years of age, had been born and lived at least the first 6 years of life in the city, and had an unequivocal water history. The main results were summarized in two tables, one for dental fluorosis and one for caries, reproduced in Tables 9 and 10, respectively.

Griffin *et al.*¹⁰ wrote that this work found adults who received a high fluoride concentration experienced 20% fewer carious surfaces. The 20% number was an interpretation from two numbers, 7.0 and 8.7, found at the upper right corner of Table 10. (Note: the unit of measure was teeth, not surfaces.) The authors, however, were less inclined to draw the kind of conclusion that Griffin *et al.*¹⁰ did. They wrote:

The picture is less obvious for dental caries. ... The assessment of dental caries in an adult population is difficult. ... First, it is often difficult to determine why missing teeth were removed. ... Second, it is not

Table 9 Number and percent of subjects by city and fluorosis classification from Eklund *et al.*⁵¹

Fluorosis	Lordsburg (n=164)		Deming (n=151)	
Normal			104	(68.9%)
Questionable			23	(15.2%)
Very mild	1	(0.6%)	17	(11.3%)
Mild	1	(0.6%)	2	(1.3%)
Moderate	37	(22.6%)	5	(3.3%)
Severe	63	(38.4%)		
Very severe	62	(37.8%)		

^{xiv} “Disparities [in dental health] were noticed across all age groups, among racial/ethnic groups, persons with lower education and income, and by smoking status.”¹¹¹

Table 10 Comparison of mean decayed, missing, or filled teeth (DMFT) and selected components by city and age of lifelong resident adults from Eklund *et al.*⁵¹

Age group	Decayed		Missing		Filled		DMFT	
	L	D	L	D	L	D	L	D
All	0.8	0.6	2.8	2.4	2.9	5.4	7.0	8.7
27–40	0.4	0.7	1.3	1.6	3.6	4.4	5.9	6.9
41–50	1.5	0.5	2.4	3.7	2.4	6.6	7.1	11.1
51–65	0.6	0.2	5.6	3.3	2.2	7.3	8.8	11.1

L: Lordsburg; D: Deming

possible to determine whether all filled teeth had a carious lesion as defined by the diagnostic criteria.

In contrast, they concluded that differences between the communities are “obvious and unequivocal” for dental fluorosis. Indeed, no one from Lordsburg escaped dental fluorosis and 76% of them were severe or very severe. At the lower concentration of 0.7 mg/l, Deming had 16% dental fluorosis, including some moderate cases.

Table 10 shows that the higher DMFT in Deming was due to a much higher filled component across all age groups. As with Grembowski *et al.*,¹⁰⁷ Eklund *et al.*⁵¹ noted that the filled component is influenced by dentists’ treatment decisions. On the other hand, the oldest age group in Lordsburg had many more missing teeth, similar to other studies that found a relationship between high fluoride exposure and tooth loss.^{112,113}

Costs of dental treatments

Costs of dental treatments consist of dental fees and lost productivity. Griffin *et al.*¹⁰ used survey data for the dental charge,¹¹⁴ which may differ from the charge in a competitive market, and therefore not be representative of the resource costs. Assumption (6) holds that all fillings are single-surface fillings. This overestimates dental costs, since a three-surface cavity does not require three times more resources than a one-surface cavity requires, in terms of either time lost or dentist’s effort. In fact, the fees in the survey were \$53.60 and \$83.27 for one- and three-surface amalgam fillings, respectively.¹¹⁴ Griffin *et al.* used the U.S. average hourly wage for the productivity cost. Average hourly wage overestimates productivity cost, since another central argument for CWF is equity, i.e. it is supposed to be particularly beneficial to low-income people.

Minimal corrections

In this section, we show how the defects in the derivation of CWF benefits, or gross savings, discussed above can be corrected.

Costs of dental treatments

The resource value of a treatment is best represented by the allowable charge from a widely accepted insurance fee schedule. Fee schedules may vary for a number of reasons, but the relative values among closely related procedures tend to be stable.

Table 11 shows the allowable charges for amalgam fillings from two large payers, one from a public payer¹¹⁵ and one from the largest commercial payer (private communication). The payments are not proportional to the number of surfaces involved, and Assumption (6) in Table 2 clearly overestimates the dental charges. Using these relativities and two assumptions a new gross savings estimate will be provided.

Our first assumption is that the average number of decayed surfaces per filling is two and the average dental fee is about that of a two-surface filling. For example, a 40% : 30% : 20% : 10% distribution of one-, two-, three-, and four-or-more-surface fillings, respectively, produces such averages using the relativities in Table 11. Our second assumption is that each equivalent two-surface filling costs 1 hour in lost wages.

Brown and Lazar¹¹⁴ reported that there were more two-surface fillings than one-surface fillings in the 1990 survey and that the number of one-surface fillings has been dropping faster despite a vastly increased number of examinations. Since the more the distribution is weighted toward more-surface decays the less gross savings there are, our first assumption likely overestimates gross savings.

Table 11 Allowed charges and their relativities for amalgam fillings from two insurance fee schedules

Surfaces	Denti-Cal (CA Medicaid, \$)	Delta Dental (San Diego area, \$)
One	39 (1)	72 (1)
Two	48 (1.23)	87 (1.21)
Three	57 (1.46)	108 (1.50)
Four or more	60 (1.54)	118 (1.64)

Using the more generous 1.23 factor from Denti-Cal to calculate a correction, the average cost per carious surface, \$54+\$18, in Step 1 is changed to

$$(1.23 \times \$54 + \$18)/2 = \$42.21 \quad (4)$$

The \$54 fee for a one-surface amalgam filling was based on a survey of about 5% of U.S. dentists in private practice.¹¹⁴ We argue that the allowed charge from a major commercial dental insurer better represents the true cost of resources, and we have an actual allowable charge of \$72 from the San Diego area (Table 11). The cost of living in San Diego is 1.43 relative to the U.S. average.³¹ Using that index would give a one-surface amalgam cost of \$72/1.43=\$50.35 today. It is reasonable then to keep the national average assumption at \$54, which is 38% higher than the current California Medicaid payment rate.

The \$18 opportunity cost was a U.S. average hourly wage. The 2010 U.S. median and mean hourly wages are reported to be \$12.68 and \$19.21, respectively.¹¹⁶ As equity is the other strongest appeal of CWF, the median wage is more appropriate than the mean wage for representing productivity loss. Substituting the \$12.68 for the \$18 in equation (4) to obtain an updated average cost per carious surface gives

$$(1.23 \times \$54 + \$12.68)/2 = \$39.55 \quad (5)$$

This value replaces the \$72 in equation (1) in Step 2. The final result is that the \$19.12 PPPY gross savings in Step 5 changes to

$$\$19.12 \times (\$39.55/\$72) = \$10.50 \text{ PPPY} \quad (6)$$

Averted caries — a consistent approach

Calculating averted caries as a product of no-CWF Incidence and CWF Effectiveness is fundamentally unsound. Griffin *et al.*¹⁰ could have derived a self-consistent averted caries directly from Brunelle and Carlos,⁷⁷ the results from which are summarized in the first six columns in Table 12.

As it was assumed that CWF benefit begins at age 6 years and the caries aversion begins after 1 year of exposure [Inputs (f) and (h) in Table 2], the first annualized data point (difference in DMFS) is at age 7 years with 1 year of exposure. This procedure provides 11 data points, as illustrated in the last three columns in Table 12. Taking the mean of the 11 data points gives the average annual DMFS difference (0.11), which can be used as the averted tooth decay surfaces PPPY.

Thus a self-consistent derivation yields an averted DMFS PPPY of 0.11, not 0.19. Applying this correction to the previous adjustment, the gross savings is further reduced to

$$\$10.50 \times (0.11/0.19) = \$6.08 \text{ PPPY} \quad (7)$$

Lack of evidence for adults

Since there is no real evidence that CWF prevents caries in adults, we present hypothetical scenarios; each scenario assumes that the caries aversion rate extends to a given age.

To calculate the estimate for each scenario, Step 4 is modified by summing the weighted costs to the cut-off age. Thus, if CWF is effective to age 19, 29, 39, or 64 years, the national average lifetime cost averted per decayed surface becomes \$32.56, \$52.98, \$74.48, or \$100.62, respectively, prior to the corrections. The ratio of each of the lifetime costs to \$100.62 is how the gross savings is reduced in each age scenario.

Table 12 Summary data from Brunelle and Carlos,⁷⁷ differences between no exposure and lifelong exposure groups, and estimate of averted caries based on the data

Age	Lifelong exposure			No exposure		Years after age 6	Difference in mean DMFS	
	U.S. population	Children examined	Mean DMFS	Children examined	Mean DMFS		Cumulative	Annual
5	2,552,751	227	0.03	229	0.10			
6	3,980,732	705	0.14	645	0.14			
7	3,578,063	764	0.36	780	0.53	1	0.17	0.17
8	3,211,415	782	0.64	757	0.79	2	0.15	0.08
9	3,332,326	766	1.05	811	1.33	3	0.28	0.09
10	3,357,708	802	1.64	710	1.85	4	0.21	0.05
11	3,179,166	716	2.12	756	2.63	5	0.51	0.10
12	3,206,386	649	2.46	687	2.97	6	0.51	0.08
13	3,229,289	616	3.43	613	4.41	7	0.98	0.14
14	3,473,894	590	4.05	600	5.18	8	1.13	0.14
15	3,552,049	504	5.53	559	6.03	9	0.50	0.06
16	3,581,737	529	6.02	551	7.41	10	1.39	0.14
17	3,045,456	515	7.01	535	8.59	11	1.58	0.14
Total	43,280,972	8,165	2.66	8,233	3.24		Average =	0.11

DMFS: decayed, missing, or filled tooth surfaces.

Thus the gross savings of \$6.08 PPPY becomes \$1.97, \$3.20, \$4.50, or \$6.08 PPPY if the CWF benefit extends to age 19, 29, 39, or 64 years, respectively.

Discussion

Corrected net savings

In the previous section, we showed how several defects in the derivation of the \$19.12 PPPY estimate of CWF benefit can be corrected. The corrected gross savings estimate is \$1.97, \$3.20, \$4.50, or \$6.08, if the CWF benefit extends to age 19, 29, 39, or 64 years, respectively.

As described earlier, the cost estimates of \$0.50 for large water systems and \$3.17 for small systems¹⁰ were not based on reality. We used a detailed engineering projection report prepared for a system that has a decade of CWF experience and has characteristics of both large and small systems to obtain a more reasonable estimate of \$3 and \$10 PPPY, respectively.

The net savings are summarized in Table 13. In short, there is minor savings only if the caries aversion attributed to CWF extends to old ages and only in large systems. Thus minimal correction to several methodological problems eliminates most of the savings. When we include the estimated cost of treatment of dental fluorosis of at least \$3.24 PPPY, there are no savings left in any scenario in Table 13.

Topical effect

There is a question whether any savings for averted caries are real, because the mechanism by which fluoride is thought to help prevent caries is topical. Griffin *et al.*¹⁰ explained that Assumption (1) in Table 2 was due to the benefit from water fluoridation being primarily “topical and post-eruptive.” The CDC¹ states that fluoride prevents dental caries predominantly after eruption of the tooth into the mouth, and its actions are primarily topical. Both articles referenced Featherstone,¹¹⁷ who stated that the effect of ingested fluoride on caries is minimal.

Current official justification for continuing promotion of CWF is that fluoride in tap water provides teeth with continuous exposure from water, beverages, and foods prepared with tap water, and that a constant low concentration of fluoride is maintained in the dental plaque and saliva all day.¹¹⁸ The first point can be left to common sense. The second point contradicts current oral hygiene recommendations concerning plaque and has been refuted concerning

saliva. The concentrations of fluoride in ductal saliva, approximately 0.016 ppm in fluoridated areas and 0.006 ppm in nonfluoridated areas, are “not likely to affect cariogenic activity.”¹¹⁹

In addition, fluoride, by ingestion or by contact, negatively affects enamel remineralization in individuals with low calcium and magnesium in teeth enamel (usually due to undernutrition).⁵⁷ Hence, CWF may increase caries in people with poor nutritional status.

Equitable?

That CWF particularly helps the poor at a very low average cost to all has been an integral argument for CWF. We briefly examine the equity aspect.

A major review of the effectiveness of CWF states “There is some evidence [strength of evidence=C] that water fluoridation reduces inequality in dental health across social classes in 5- and 12-year-olds [in England] ... The small quantity of studies, differences between these studies, and their low quality rating, suggest caution in interpreting these results.”⁷¹

In Appendix 5, we point out two studies missing from the review of Truman *et al.*⁸⁰ In the first study Szpunar and Burt⁴⁹ reported that a fluoride concentration of 1.0 or 1.2 mg/l prevented caries, but 0.8 mg/l did not. (The current CWF range is 0.7–1.2 mg/l, and HHS proposed to decrease it to 0.7 mg/l.)³ This study chose a predominately white township bordering Detroit, instead of the largely black and long fluoridated Detroit, to represent a fluoridated community. Burt *et al.*¹²⁰ reported that only 0.2% of low-income adults in Detroit in the 14–35 age group (born after CWF started in 1967) were caries free (compared to 55% of children up to age 12+ in the unfluoridated community in Szpunar and Burt).⁴⁹

In the second study, Shiboski *et al.*¹²¹ found that the prevalence of early childhood caries was not affected by fluoridation status. Among Head Start (low income) children, the most fluoridated ethnic group (Asians, with 69% in fluoridated areas) had the worst tooth decay status. Among non-Head Start children, the most fluoridated ethnic group (Asians, with 81% in fluoridated areas) had tooth decay rates similar to those of white Head Start children, with 12% in fluoridated areas.

Truman *et al.*⁸⁰ stated: “The current burden of poor oral health continues to disproportionately

Table 13 Present-day, corrected estimates of net savings (\$) per person per year from water fluoridation

System size	Cost (\$)	Benefit (\$) ⇒	CWF benefit extends to age			
			19	29	39	64
			1.97	3.20	4.50	6.08
Large	3		–1.03	0.20	1.50	3.08
Small	10		–8.03	–6.80	–5.50	–3.92

affect communities with large numbers of African Americans, American Indians, Hispanics, the poor, and the disabled of any race or ethnic group.” (See also CDC.)¹¹¹ This was not the case historically. Citing many studies published between 1933 and 1947, Finn⁷³ stated that blacks had less caries than whites. On the other hand, recent data indicate that dental fluorosis is more prevalent among blacks and Hispanics,^{47,111} suggesting that lack of fluoride is not an explanation for their poorer oral health.

Conclusion

For decades, the U.S. federal and state governments have promoted CWF to improve dental health of residents at low costs. Yet, in spite of the presumed savings in dental costs to Americans due to widespread use of CWF, employment of dentists is projected to grow by 16% between 2012 and 2022 (vs. 11% for all occupations),¹²² and cosmetic dentistry in the U.S. has grown to be a multi-billion dollar industry.¹²³ We have shown that the promise of reduced dental costs was based on flawed analyses. In particular, the primary cost-benefit analysis used to support CWF in the U.S. assumes negligible adverse effects from CWF and omits the costs of treating dental fluorosis, of accidents and overfeeds, of occupational exposures to fluoride, of promoting CWF, and of avoiding fluoridated water. In assessing the benefits, it ignores important large data sets and assumes benefits to adults that are unsupported by data. Thus this analysis, as well as other economic analyses of CWF (Appendix 2), falls short of reasonable expectations for a cost-benefit analysis from a societal perspective. Minimal correction of methodological problems in this primary analysis of CWF gives results showing substantially lower benefits than typically claimed. Accounting for the expense of treating dental fluorosis eliminates any remaining benefit.

Appendix 1: State governments repeating the \$1 saves \$38 claim

This appendix gives a list of U.S. State governments, other U.S. government agencies, and Canadian sources that repeat the claim that \$1 saves \$38. Mississippi and Oregon did not repeat CDC's claim of \$1 saves \$38. We include them in the list because they repeat the net savings PPPY estimated by Griffin *et al.*¹⁰ Mississippi provided its own cost estimate (\$1 to \$2 PPPY), but the estimated net savings are from Griffin *et al.*¹⁰ All URLs were last accessed on August 13–15, 2013, except Canadian sources, which were last accessed on October 15, 2013. † indicates state legislative records. The list may not be exhaustive.

1. *Alabama*: “For most cities, every \$1 invested in fluoridation saves \$38 in dental treatment costs.” http://medicaid.alabama.gov/documents/2.0_Newsroom/2.5_Presentations/2.5_Medical_Services_Presentations/2.5_OHCA_Goode_Fluoridation_9-23-10.pdf

Appendix 2: Other cost-benefit studies

Earlier economic evaluations of CWF have been reviewed by White *et al.*¹¹ Mariño *et al.*¹²⁴ summarize a number of studies for caries prevention programs but do not discuss those studies in detail. Griffin and Jones¹²⁵ reviewed Mariño *et al.* Other studies examined dental insurance data and did not find CWF to be associated with lower utilization or costs of dental services.^{126,127}

In this appendix, we comment on several additional recent CWF cost-benefit studies: Campain *et al.*¹²⁸ assessed the impact of changing dental needs over time on the cost savings from CWF in Australia. O’Connell

*et al.*¹²⁹ estimated the cost savings associated with CWF in Colorado and potential savings if the unfluoridated communities were to implement CWF. Wright *et al.*¹³⁰ investigated whether it would be cost-effective to fluoridate water supplies that were not fluoridated in New Zealand. Kroon and van Wyk¹³¹ examined whether water fluoridation is still a viable option to reduce dental caries in South Africa by addressing concerns about cost and effectiveness. Tchouaket *et al.*¹³² estimate the cost savings in Quebec resulting from CWF; since this is a 2013 paper claiming to use an “innovative approach” we will comment on it separately.

Costs

As with Griffin *et al.*,¹⁰ both O’Connell *et al.*¹²⁹ and Kroon and van Wyk¹³¹ based their cost estimates on Ringelberg *et al.*¹⁴ Wright *et al.*¹³⁰ hypothetically estimated capital and annual operating costs “by consulting equipment providers and operators of fluoridation systems.” These studies all adopt the assumption of a 15-year replacement schedule except Kroon and van Wyk,¹³¹ who are more detailed in the cost aspect and have a separate replacement schedule of 8 years for mechanical and electrical plant. On the other hand, Campain *et al.*¹²⁸ used a simple A\$0.27 PPPY but provided no details.

Estimates of averted caries

O’Connell *et al.*¹²⁹ essentially used the base case from Griffin *et al.*¹⁰ They used the 25% value for Effectiveness. For Incidence, they used the base case (middle row in Table 6 in the main text) with minor changes: They reduced the 0.77 and 1.09 values by 20.9% for the secular trend, but decided that the 0.43 value for age 45–65 years was too low; instead they used 1.08 and 1.31 for ages 45–64 years and ages 65 years and older, respectively, through consultation with Griffin. The resulting average averted caries is 0.2 DMFS, almost the same value (0.19 DMFS) as in Griffin *et al.*,¹⁰ but O’Connell *et al.* applied it to all ages from age 5 years.

Campain *et al.*¹²⁸ assumed uniform but changing effectiveness for all ages from age 6 years. They picked a value within the range of numbers reported from a set of references, including several discussed in this article.^{77,107,108,133} Thus they assumed that CWF effectiveness was 50% in the 1970s, 30% in the 1980s, and 25% in the 1990s. For Incidence they constructed a matrix of year versus age range from their literature search and imputed values where information was missing.

Kroon and van Wyk¹³¹ cited the 15% Effectiveness from Petersen *et al.*,¹³⁴ and also modeled the benefit using 30% and 50%. This Effectiveness is applied to teeth, not surfaces as in the other studies. For Incidence they used local survey data by city. The

method, according to Kroon and van Wyk,¹³⁵ is to divide the DMFT survey of, say, 15-year-olds by $15 - 6 = 9$ and assume it is the same for people of all ages, including those age 6 years and less. The authors noted that the mean DMFT for 12-year-old South African children decreased from 1.73 in 1988–1989 to 1.05 in 1999–2002 in this unfluoridated country.

Wright *et al.*¹³⁰ did not try to estimate a value for Effectiveness. For children aged 4–13 years, they compared treatment data for restorations and extractions for both deciduous and permanent teeth to calculate savings on dental fees. They used 1996 Wellington and Canterbury data without supporting the selection, since such data are available for all New Zealand and for all years. For ages 14–34 years, they used a 0.29 averted DFS number from Grembowski *et al.*¹⁰⁷ (but increased it to 0.59 surfaces for Maori) and assumed no effectiveness after age 34 years.

Costs of dental treatments

On productivity loss, Campain *et al.*¹²⁸ and O'Connell *et al.*¹²⁹ used approaches similar to Griffin *et al.*¹⁰ Wright *et al.*¹³⁰ and Kroon and van Wyk¹³¹ did not include productivity cost. Below, we note the variations in the methods of estimating dental fees in these studies.

Kroon and van Wyk¹³¹ estimated caries in DMFT and used the average cost of two-surface fillings for the dental charge for each DMFT. Wright *et al.*¹³⁰ used the treatment database from Wellington and Canterbury for children ages 4–13 years and included both deciduous and permanent teeth. For those ages 14–34 years, they calculated the cost of a single-surface filling using an average dentist hourly rate (with inflation) and the 15 minutes time needed to put in the filling. They assumed that fillings are replaced every 8 years.

Campain *et al.*¹²⁸ and O'Connell *et al.*¹²⁹ attempted to include more-surface fillings, composite fillings, and crown or extraction costs. However, the calculations lack transparency, and there are questions as to whether the interaction between extractions and restorations is handled properly in the latter. The most serious problem with the two studies is that they calculated the dental fees plus productivity cost on a *per visit* or *per service* basis, rather than normalizing that cost to a *per surface* basis, because one visit or service may treat more than one surface. By multiplying the estimated averted DMFS by a cost per visit or service rather than a cost per surface, they overestimated the averted costs of dental services. In addition, crowns or extractions are not always due to caries, but may have other causes. Thus these approaches lead to a far worse overestimation than Assumption (6) in Griffin *et al.*'s analysis.¹⁰

Tchouaket *et al.*¹³²

A paper by Tchouaket *et al.* claims to use an “innovative approach” to assess the economic value of water fluoridation for Quebec, in which only 2.7% of the population is fluoridated.¹³² The presentation lacks critical information and contains fundamental errors. The authors claim that their analysis “adopted a societal perspective that allowed us to track all the costs and effects of the intervention.” However, they did not include or mention the costs of treating dental fluorosis or any of the costs we discussed under “Other costs.” All \$ signs in this section are Canadian dollar, C\$.

Tchouaket *et al.* produced \$1.93, \$2.05, or \$2.25 PPPY as the costs of CWF, using information from the few fluoridated municipalities in Quebec. Supposedly, the three values correspond to using 3%, 5%, or 8% to amortize the subsidies received by these municipalities over 20 years. They listed several salary rates but provided no other quantitative information, thus readers are not able to repeat any calculations or confirm the numbers.

For CWF benefits, Tchouaket *et al.* did not try to estimate averted caries. Instead, they estimated the yearly costs associated with restorative dental treatments in Quebec to be \$532.08, \$532.87, or \$534.05 PPPY, depending on discount rates. They compared these with the cost values above at various hypothetical values of CWF effectiveness, and claimed that CWF is cost-effective even at 1% effectiveness and that Quebec saves more than \$560 million a year at an “expected average effectiveness of 30%.”

It should be noted that the \$532–\$534 PPPY *restorative* expense exceeds the actual per capita spending on *all* dental services in Canada, which was reported to be \$380.83 in 2009 and \$399.10 in 2011.^{136,137} Tchouaket *et al.* confused untreated tooth decay and dmft/DMFT (decayed, missing, or filled teeth) — only untreated decay (“d” or “D” in dmft/DMFT) requires a restoration service. A filled tooth might need a replacement at some point in the future, but definitely not every year.

The authors calculated the number of teeth restored in a year by multiplying the number of persons who used dental services within the past year, by age group, times the dmft/DMFT index for that age group. First, the average dmft/DMFT values given in the paper are clearly cumulative, not an annual increment. Only a small percentage of these would correspond to untreated decay that requires a restoration service.^{xv} Second, Tchouaket *et al.*

^{xv} While the level of caries experience is very high in Quebec adults aged 35–44 years, only 1.8 out of 148 surfaces are decayed (in need of treatment), on the average, and more than half of the people (55.5%) have no decayed surfaces.¹³⁸

apparently failed to recognize that routine dental cleaning and examinations are common in developed countries, thus having used dental services does not equate to having had a tooth restored.

Data in the paper indicate that 25–61% of children (depending on age) were caries free, while 78–91% had visited a dentist in the past year; thus many of the children utilizing dental services had not had any restorations, that year or previously. The 35–44 age group had an average 20 DMFT, and 69% used dental services in the past year. Tchouaket *et al.*'s calculations assumed that each of the 69% (724,000 people) had 20 restorations in 1 year. The correct interpretation of the data is that the average Quebecer 35–44 years old had accumulated 20 DMFT between the age of about 6 and the time of the survey, about 29–38 years, or approximately 0.5–0.7 new DMFT on average per year. This is consistent with the increments of 0.2–0.6 dmft/DMFT for children that can be derived from other information in the paper.

Tchouaket *et al.* summarized fees for treatment of one cavity, including transportation costs and lost wages. A total fee for each of three categories (by type of tooth and age group) was not provided. The text and table in the paper disagree on the calculation of transportation costs, and some information in the summary table is not explained. The text indicates that those age 14 years or older require two separate trips, one for a complete examination and one for the restoration to treat one cavity. However, fees for routine dental exams should not be counted toward costs that can be saved by CWF.

The authors appear to have taken their calculated number of teeth restored for a given age group times the cost per restoration for that age group to obtain the total cost of restorations in one year for that age group. The combined total cost for the three age groups included in the analysis (5–8, 11–14, 35–44;

1.7 million people total) appears to have been averaged over the entire population of Quebec (7.9 million people) to obtain their final average of \$532–\$534 PPPY. This brings up the question of whether other age groups (9–10, 15–34, and 45+) were assumed to have no restorations. However, averaging (incorrectly) over the entire population rather than over the relevant age groups compensates partly for the great overestimation in the number of restorations per year.

The three values \$532.08, \$532.87, or \$534.05 supposedly differ in the different discount rates (3%, 5% and 8%) used to calculate repeat treatment. Estimating the dental cost for replacement services is not new, but the scant description provided in two sentences does not show what the authors have done or allow readers to understand why the three results are so close.

Tchouaket *et al.* admitted that basing the 2010 economic value on caries prevalence data more than a decade old is a limitation. This is a legitimate concern due to the well known “secular decline” of caries in developed countries.⁷² However, the authors argued that because the percentage of the Canadian population with at least one dental cavity has remained stable at 96%, the average DMFT in Quebec likely has remained the same or even increased. Actually, the 96% figure applies only to dentate adults aged 20–79 years. For children aged 6–11 years and adolescents aged 12–19 years, the corresponding national figures are less than 60%.¹³⁶ Factual error aside, this argument reflects their confusion with the differences between cumulative DMFT and new caries and with properly defined populations.

Appendix 3: Accidents, overfeeds and damages

A number of accidents, overfeeds, and damages caused by CWF are summarized in Table 14.

Table 14 Examples of accidents, overfeeds and damages from CWF

Location and date	Description
1. Deltona, FL September, 1994	“A tanker truck cracked open on I-4 near Deltona ... and released 4,500 gallons of fluorosilicic acid in one big whoosh.” It was “one of the worst chemical spills in Volusia county’s history.” 2,300 people were evacuated, and more than 50 people were sent to hospitals with complaints of skin and respiratory irritations, including some hours after the spill. Motorists were instructed not to wash off the chemical film with water as that could cause respiratory problems to anyone nearby. EPA officials felt it was “a significant health hazard as far as ground water.” The agency ordered around-the-clock cleanup on I-4 that lasted days.
2. Lowell, AR December, 1996	Beaver Water District fluoridated Fayetteville with fluorosilicic acid and Springdale with sodium fluorosilicate powder prior to 1992. When CWF was resumed in 1996, adding Rogers and Bentonville, the decision was made to use the powder, as fumes from the liquid had severely damaged the injection facility in the past.
3. Malvern, AR March, 1997	A water plant operator at the Kimzey Regional water plant was sprayed by fluorosilicic acid at work. According to his 2012 personal account, he became 100% disabled for almost 14 years and still requires large amounts of pain medicine. He suffered permanent health damage, including losing all his teeth.
4. Charleston, SC August, 2000	A worker accidentally put the wrong chemical in the fluoride tank in the Hanahan Water Treatment Plant. The chemical “reacted; it released a large amount of heat; the fiberglass essentially melted; the gas flowed; it just burst.” This resulted in a 20,000-gallon acidic mess. The total bill for cleanup and repairs was about \$250,000.

Table 14 Continued

Location and date	Description
5. Wakefield, MA August, 2000	An overdose of fluoride seeped into the town water supply. Officials made door-to-door warnings around the pumping station. The public became aware only after a local news station called the town. Authorities said there were no reports of illness; but Linda Collins disagreed, "I was crazy dizzy and I had the runs. I think it was woefully inadequate the way they notified us," she said. "Because they didn't."
6. Coos Bay, OR October, 2000	At least 3.5 million gallons of partially treated sewage has spewed into the Coos Bay after 400 gallons of fluorosilicic acid flowed into a sewage treatment plant, killing its bacteria-munching organisms.
7. Fort Wayne, IN February, 2001	About 6,000 gallons of fluorosilicic acid drained from the lower level of the filtration plant into the sewer. The fluoride tank overflowed, and caustic fumes filled the area causing difficulty breathing, chest pains, severe headache and sore eyes in plant workers. Four workers were treated in the hospital.
8. Marlboro, MA October, 2003	A valve malfunction allowed a concentrated level of fluoride to flow into the water system. Workers went door to door to alert nearby customers, flushed water mains, and shut down the plant for some time. Residents and businesses were advised to take extreme care when flushing their pipes, and not to come into contact with the water, which could cause burning, skin irritation, or both.
9. Westminster, MA November, 2005	Emergency crews responded to a chemical spill at the Regional Water Treatment Facility after one of the storage tanks leaked about 750 gallons of fluorosilicic acid. An operator and two colleagues were transported to the hospital.
10. Moncks Corner, SC April, 2006	In the Santee Cooper water treatment plant, a water plant security guard became sick after she walked through a cloud of sodium fluorosilicate. The complaints included having trouble breathing, feeling like something was constantly caught in her throat, and "in the following weeks, Morris's hair started falling out, she developed a rash on her arms and back, and she continued to be wracked with convulsive fits of coughing."
11. Nashville, TN March, 2007	Valve malfunctions caused a fluoride overfeed in Harpeth Valley Utilities District. The Incident Event Log showed that an operator noted abnormal measurements starting at 12:40 a.m. 9 March 2007. Plant workers went through the facility shutting off equipment, conducted frequent water samplings and measurements, performed aggressive and continuous flushing, and contacted authorities. They also prepared for door to door public notifications, fielded incoming calls, responded to media requests, and continued sampling throughout the distribution systems until 17 March 2007. They also retained an outside engineering service to review and provide recommendations for the chemical feed systems.
12. Salt Lake City, UT August, 2007	A fluoride tank overflowed at a water treatment plant. Fluoride (1,500 gallons) spilled into a pond, resulting in an advisory to avoid Parleys Creek for several days. Utility workers used sandbags and a makeshift earthen dam to contain the chemical. Four hazmat teams worked to keep the fluoride from flowing beyond a park at the base of Parleys Canyon. Water was released from a reservoir to flush the chemical from the creek.
13. Conway, AR July, 2008	A 42-inch water pipe corroded to the point of failure, due to the fluoride injection port being mounted too close to a chlorine injection port, necessitating the shutdown of a portion of the plant that was completed only in 2005.
14. Chesterfield, MO February, 2009	Approximately 200 gallons of fluoride spilled from a ruptured tanker truck, which was carrying 4,000 gallons of the chemical at Missouri American Water's central plant. The truck's driver and two employees from the plant were taken to an area hospital.
15. Anchorage, AK April, 2010	A system malfunction at Fort Richardson Water Treatment Plant caused excess fluoride in the drinking water supply. Officials warned "anyone who lives, works on or visits the two posts in Anchorage not to drink the water ... The water also should not be used to brush teeth and wash or cook food. Any ice cubes ... should be thrown out."
16. Asheboro, NC June, 2010	Tank malfunction caused approximately 60 gallons of fluoride to be dispersed into the water system. The news release said: "Residents who consumed a large quantity of water during this period may possibly experience short-term effects such as an upset stomach, vomiting, or diarrhea. The temporary effect from skin contact, such as showering, might include slightly irritated skin."
17. Rock Island, IL March, 2011	Hazmat crews were called to the Rock Island water treatment plant for a spill of hydrofluorosilicic acid from a tanker truck. As plant employees evacuated, crews began suiting up, working quickly to stop the leak that had begun eating through concrete.
18. England, AR April, 2011	A worker mistakenly poured about 10 to 20 gallons of fluoride into a container holding around 150 gallons of bleach. It created a dangerous gas and led to an evacuation of several businesses near the water treatment plant. The worker and an employee from a nearby business were treated for breathing problems. The county Hazmat team cleaned up the area 3 hours later.
19. Hickory, NC August, 2011	The City transferred \$106,713 from capital reserve to maintenance and repair to pay for refurbishing the chemical room and to replace two fluoride tanks. The tanks leaked enough fluoride to degrade the concrete around the containment area and floor.
20. Martinsville, VA February, 2012	The city had to pay \$16,450 in penalties after about 1,000 gallons of fluorosilicic acid leaked from a tank at the city water treatment plant. The spill caused the deaths of an estimated 4,445 fish. Officials said that the ground near the spill absorbed quite a bit of the acid, and how much went into the creek was unknown. "Fluorosilicic acid is 'a very strong acid ... with a very corrosive effect on any metals it touches,' and corrosion caused the pump to fail."
21. Memphis, TN July, 2012	Fluorosilicic acid tank failure along with containment failure caused approximately 1,500 gallons of the acid to be released onto ground at the public utility. Approximately 1.5 acres were impacted. Workers cordoned off the area and placed berm along the west property line to prevent further runoff. The impacted area was to be excavated and soil properly disposed of.

CWF: community water fluoridation.

Additional incidents of acute poisoning have been described elsewhere.^{139,140}

Appendix 4: More on CWF effectiveness in adults

We examine two recent articles claiming to show effectiveness of CWF for adults: Slade *et al.*¹⁰⁹ applied SAS procedures on data from a 2004–2006 Australian survey of adults. Griffin *et al.*¹¹⁰ performed a meta-analysis of 20 studies that sought to “examine the effectiveness of self- and professionally applied fluoride and water fluoridation among adults.”

Slade *et al.*¹⁰⁹ concluded that high lifetime fluoridation exposure was associated with 11% and 10% lower DMFT (or 30% and 21% DFS) among pre-1960 and 1960–1990 birth cohorts. We show that what is attributed to CWF is better explained by differences in age distributions.

Griffin *et al.*¹¹⁰ combined CWF with self- and professionally applied fluoride, which are topical treatments

and very different from CWF in many respects, e.g. the applications or dosages are controllable; it does not appear reasonable to combine them in a meta-analysis. They “used a random-effects model, which assumes that each study was randomly selected from a hypothetical population of studies,” without discussing the applicability of the model. We focus on the CWF-related studies. These authors concluded that the CWF effectiveness was a 27.2% reduction in caries. We are not able to reproduce this result, which was based on four studies reporting DMFT and one study reporting DMFS; there was no explanation how the different units were handled. As with Slade *et al.*,¹⁰⁹ Griffin *et al.*¹¹⁰ failed to adequately account for different age distributions.

Slade *et al.*¹⁰⁹

Thirty dentist-examiners conducted the oral examination in this national survey. For participants aged <45 years, only teeth extracted because of dental caries or periodontitis were counted as missing, but all absent teeth for older people were counted. Fluoridation exposure was determined by residential history, and a value of 0, 0.5, or 1 was assigned if the fluoride concentration at the location was less than 0.3, between 0.3 and 0.7, or greater than 0.7 mg/l, respectively. A value of 0.5 was assigned to all localities in New Zealand, Canada, or the U.S. and 0 to all other foreign localities, without regard to the actual CWF status of the locality.

A significant portion of CWF exposure status was imputed: 3,779 people were considered to have valid exposure data (Complete case), meaning less than 50% of the person’s residential data were missing; the missing years were assumed to be their average observed fluoridation exposure. The exposure status of the remaining 1,726 people with more than 50% missing residential data was imputed by substituting with the status of a random sample from the 3,779 people who belonged to the same geographical stratum and 10-year age group.

Samples were divided into four levels of CWF exposure, i.e. <25% (negligible), 25 to <50%, 50 to <75%, and ≥75% (prolonged) of lifetime. Given the way CWF exposure was determined, the accuracy of this classification is questionable.

Slade *et al.* use unspecified linear regression models to “age-adjust” caries experience and fluoridation exposure. They draw the main conclusion of effectiveness by comparing the “age-adjusted” DMFT/DFS scores of the “prolonged” and “negligible” groups for the cohorts born before 1960 and those born between 1960 and 1990, respectively. The observed DMFT/DFS scores are not provided. The “age-adjusted” DMFT/DFS scores are given by birth cohort and exposure group (Table 15).

Table 15 “Age-adjusted” DMFT and DFS from Slade *et al.*¹⁰⁹

	% of Lifetime exposed to CWF			
	<25%	25–50%	50–75%	≥75%
Pre-1960 birth cohort				
DMFT	21.75	20.90	21.62	19.21
DFS	37.90	35.83	37.00	29.97
1960–1990 birth cohort				
DMFT	8.91	9.53	8.88	7.61
DFS	15.89	18.01	15.65	12.41

CWF: community water fluoridation; DMFT: decayed, missing, or filled teeth.

The scores reported in Table 15 are not consistent with the conclusion that CWF exposure is effective. The scores for the two middle exposure levels were interpreted as “suggested a dose-response relationship.” This is an unreasonable explanation, as an apparent difference in DMFT/DFS is lacking among the first three exposure categories. In addition, exposure levels were defined by cumulative residential status relative to age. For example, a person who lived in places with a fluoride concentration of 1 mg/l for 50 years and 0.25 mg/l for 20 years (treated as 0 mg/l, as 0.25 is less than 0.3) would have been assigned to the 50 to <75% exposure group, which, according to their results, gets no benefit relative to someone living all 70 years in nonfluoridated areas.

There are also questions regarding the validity of their use of linear regression models to “age-adjust.” Calculation from data provided by Slade *et al.* (shown in Table 16) reveals that some cells have few or no people. In particular, the category of ≥75% exposure level is clearly much younger than the other three exposure categories. Given the large difference in DMFT/DFS between the pre-1960 and 1960–1990 birth cohorts (Table 15), and the large difference in age distributions between the first three exposure categories and the fourth category (Table 16), it is not surprising that the ≥75% exposure category would have lower DMFT/DFS scores than the other exposure categories. Hence the differences in caries attributed to CWF between the <25% and

Table 16 Number of people and age distributions in the 2004–2006 Australian National Survey (calculated from information in Slade *et al.*¹⁰⁹)

	% of lifetime exposed to CWF				
	<25	25–50	50–75	≥75	All categories
15–24	65	10	17	154	246
25–34	91	19	39	268	416
35–44	174	103	187	301	765
45–54	177	143	365	108	792
55–64	212	236	394	0	842
≥65	192	393	134	0	718
Total	910	903	1,135	831	3,779

CWF: community water fluoridation.

$\geq 75\%$ exposure groups are probably due to inappropriate handling of age distributions.

There are other unexplained discrepancies. For example, the differences in DMFT or DFS between the $<25\%$ and $\geq 75\%$ exposure groups given in the text are not consistent with the numbers reproduced in Table 15. In particular, the DFS difference in the pre-1960 cohort was said to be 11.10 or 30%, but the numbers indicate 7.93 or 21%.

Griffin *et al.*¹¹⁰

This 2007 article included nine CWF studies (Table 17).^{51,107,133,142–147} Few, if any, of the studies can be considered high quality studies appropriate for examining the effects of CWF. Four studies involved concentrations greater than those used for CWF (0.7–1.2 mg/l).^{51,133,143,145} In all, but one study,¹⁴⁶ the examiners were probably not blind to the location of a subject's residence. Eight studies were cross-sectional, and the towns compared may have simply differed for reasons having nothing to do with CWF. The one study categorized as "prospective" is in essence a cross-sectional study that compares caries increment over an 18-month period, since no "intervention" was started or changed at the onset of the period.¹⁴³

Only four of the nine studies were conducted in the U.S. Of these, two were examined earlier in this paper.^{51,107} Below we offer a few general remarks, followed by comments on the remaining studies, especially the other two U.S. studies.^{142,143}

As we discussed earlier, assessment of dental caries in adults is difficult. Wiktorsson *et al.*¹⁴⁴ described difficulties in judging caries prevalence based on fillings (due to practices such as preventive fillings for discolored fissures on occlusal surfaces) and in defining new caries incidence, since the majority of the primary caries lesions are only enamel lesions, possibly arrested caries in many cases.

In some studies,^{133,145,146} the reported age distributions suggest that the low fluoride groups were older than the fluoride groups. Griffin *et al.*¹¹⁰ do not seem to have considered this difference in the age distributions in their analysis.

In the context of testing the hypothesis that adults benefit by continuing to drink fluoridated waters, the

progression of the differences in caries is important. Englander and Wallace,¹⁴² Murray,¹³³ and Stamm *et al.*¹⁴⁵ each reported narrowing of the differences in mean DMFT between the low fluoride and fluoride groups with increasing ages for lifetime residents. The logical conclusion is that drinking fluoridated water is not helpful beyond a certain age.

Englander and Wallace¹⁴² examined 896 and 935 adults aged 18–59 years from two Illinois towns, Aurora (1.2 mg/l) and Rockford (0.1 mg/l, referred to as "fluoride deficient"). All subjects were examined by the first author. The caries experience was found to be significantly less in the subjects from Aurora, which was attributed to the different fluoride levels in their drinking water. We offer some observations that disagree with that conclusion.

The differences in mean DMFT presented for the two towns were 5.22, 8.14, 6.62, 5.59, and 5.76 for the 18–19, 20–29, 30–39, 40–49, and 50–59 years old age groups, respectively. The mean years of consuming the respective waters in either city were increased by about 10 years for each additional 10 years age group. However, the difference in mean DMFT decreased for age groups above 29 years (for DMFS, the corresponding differences in the means decreased slightly for ages 30–39 years, but decreased substantially for ages >39 years). If the caries difference is to be attributed to fluoride, are we to conclude that after age 29 years, consuming water with 1.2 mg/l fluoride increases caries?

The study groups from the two cities were said to have similar socioeconomic structures, but there are questions as to how similar the two groups really were. Almost everyone in Aurora (pop. 65,000) and more than half the population of Rockford (pop. 130,000) were contacted. It was found that 2% of those in Aurora over 20 years old were toothless, yet the figure was 14% for Rockford. (Anyone with less than 10 teeth was not invited to participate. The percentages of people contacted who had 1–9 teeth were not given.) A sevenfold difference in the toothless population may indicate an economic difference. Even though the edentulous people were not included in the study, the authors appeared to consider the figures representative, as they tried to adjust the measurements by adding the

Table 17 Summary of community water fluoridation (CWF) studies included in Griffin *et al.*¹¹⁰

Study	Study location	Type of study	High fluoride (>1.2 mg/l)
Eklund <i>et al.</i> ⁵¹	USA	Cross-sectional	3.5 mg/l
Grembowski <i>et al.</i> ¹⁰⁷	USA	Cross-sectional	
Murray ¹³³	Great Britain	Cross-sectional	1.5–2.0 mg/l
Englander and Wallace ¹⁴²	USA	Cross-sectional	
Hunt <i>et al.</i> ¹⁴³	USA	"Prospective"	0.7–1.5 mg/l
Wiktorsson <i>et al.</i> ¹⁴⁴	Sweden	Cross-sectional	
Stamm <i>et al.</i> ¹⁴⁵	Canada	Cross-sectional	1.6 mg/l
Thomas and Kassab ¹⁴⁶	Great Britain	Cross-sectional	
Morgan <i>et al.</i> ¹⁴⁷	Australia	Cross-sectional	

2% and 14% toothless figures into the DMFT figures to raise the total percentage difference.

Englander and Wallace¹⁴² reported their results in DMFT as well as in DMFS. (They wrote that differences in dental caries experience were more striking when evaluated by means of DMF tooth surfaces.) Griffin *et al.*¹¹⁰ chose to use the numbers in DMFS. (The ratio of DMFT between the two towns appears to be similar to the ratio of DMFS according to Griffin *et al.*,¹¹⁰ but that is because they incorrectly listed the value for the filled component instead of the DMF for Aurora.)

Hunt *et al.*¹⁴³ reported new caries incidence over an 18-month period for 424 adults aged 65 years and older from a “narrowly defined geographical area” in two rural Iowa counties. Of these subjects, 174 were lifelong residents of “fluoride deficient” nonfluoridated communities, and 250 had lived in fluoridated communities (0.7–1.5 mg/l) for various lengths of time. Those who had 5–30 years of residence in fluoridated communities had comparable or worse new caries incidence compared to the lifelong nonfluoridated subjects. The authors thus focused on the remaining 101 persons with more than 30 years of residency in fluoridated communities (40% of the fluoridated sample) to draw the conclusion of effectiveness. Griffin *et al.*¹¹⁰ used only the 77 persons with more than 40 years of residency in fluoridated communities (31% of the fluoridated sample). As mentioned above, one would be tempted to conclude from Englander and Wallace¹⁴² that drinking fluoridated water after age 29 years does not work. Here, we learn that drinking it for less than 30 or 40 years does not work.

Hunt *et al.*¹⁴³ used a cross-sectional approach to compare baseline characteristics of the two groups for those with more than 30 years of residence. After at least 30 years of exposure to fluoridated water, no statistically significant difference in DFS (coronal or root caries) was noticed. In fact, Hamasha *et al.*, describing the same study population, did not even mention fluoride as a possible factor in the long-term caries experience.¹⁴⁸ Apparently, only in this 18-month period was a difference observed and attributed to fluoride. In a companion paper from the same study, Hunt *et al.* indicated no significant correlation between tooth loss and residence in a nonfluoridated community.¹⁴⁹

Murray¹³³ reported on two towns in Great Britain, one with high fluoride (1.5–2 mg/l) and one with low fluoride (0.2 mg/l). Data were reported in 5-year age groups for general samples and for dentate samples. One interesting finding was that the prevalence of edentulous persons by age was strikingly similar between the two towns, reaching about two-thirds by age 60–65 years. In the author’s terms, the “M”

component of the DMFT score was similar in both groups. However, one way to look at this is that fluoride ingestion had little or no effect on the likelihood that a person would have a full set of dentures by age 60–65 years. The difference in mean DMFT was fairly constant in the earlier age groups and significantly narrowed from around age 40 years in the general sample. (The pattern of narrowing difference in DMFT persists after removing edentulous samples.) Murray’s samples differed greatly in their age distributions, with the high fluoride group having approximately twice the fraction (33.2% vs. 16.5%) of people in the 20–24 age group and a substantially smaller fraction (27.1% vs. 44.3%) in the 40–65 age groups. Griffin *et al.*¹¹⁰ apparently included these samples without considering that it might not be appropriate.

Wiktorsson *et al.*¹⁴⁴ compared adults 30–40 years old in Swedish towns with 1 or 0.3 mg/l fluoride. Griffin *et al.*¹⁰⁷ indicate blinded examiners and unspecified fluoride concentrations, but these descriptions do not fit the actual paper — a single examiner performed examinations in the respective communities and was unlikely to have been blind to subjects’ geography. Persons with non-representative water sources were not examined. After discussing difficulties in scoring caries in adults, Wiktorsson *et al.*¹⁴⁴ report that the community with “optimal” fluoride had “significantly better” dental health status. However, without summary data for age subgroups, the picture is not entirely clear — the presented scatter plots for filled surfaces and for decayed surfaces (for ages 31–43 years) do not appear to suggest a benefit for continuing consumption of fluoridated water. (This study reports in tooth surfaces only and uses linear regression analysis.)

Stamm *et al.*¹⁴⁵ deal with 1.6 and 0.2 mg/l fluoride in Canada, and the examiners were not blind to their subjects’ place of residence. The study excluded people with fewer than eight teeth. Griffin *et al.*¹¹⁰ included the 17–19 year old group in the total sample from Stamm *et al.*,¹⁴⁰ although the 15–19 year olds in Murray¹³³ were excluded. The low fluoride group included only 1.5% in that age group, versus 6% in the fluoride group. Ages 60+ years made up nearly 18% of the low fluoride group but only 12% of the fluoride group. With respect to progression, the differences in mean DMFT between the high and low fluoride groups decreased with the older age groups, from 5.1 at ages 30–39 years to 1.7 for ages 60+ years.

Thomas and Kassab¹⁴⁶ included only females up to 32 years old, while they were hospitalized to give birth. A single hospital was used by women from a fluoridated island community (Anglesey) and several nonfluoridated mainland communities in Wales (United Kingdom); lifelong residents were included in the study. Although the authors indicate no

significant differences in age group structure of the samples from the two areas, the data show that Anglesey had more in the youngest (<20) age group, 24.1% versus 12.9% and fewer in the oldest (25–29 and 30–32) age groups, 30.0% and 5.9% versus 36.5% and 9.6%. The island of Anglesey was chosen for a demonstration fluoridation study in the 1950s. The experiment was terminated after only 5 years and the whole island was fluoridated based on the mean dmft index for 5-year-old children.

Morgan *et al.*¹⁴⁷ analyzed data for a group of Royal Australian Navy recruits, mostly males, ages 15–24 years, and with limited education. Griffin *et al.*¹¹⁰ used only the results (mean DMFT scores by fluoride history) for 20–24 year olds (208 recruits). Morgan *et al.* indicated only that approximately 20% and 30% of the total sample (1,100 recruits) were considered “fluoridated” and “nonfluoridated” (determined by residential history), respectively, and included in the calculation of the mean DMFT scores. Griffin *et al.* used the percentages to impute the sizes of the “fluoridated” and “nonfluoridated” groups to be 42 and 62, respectively.

Appendix 5: More on the CWF effectiveness in Truman *et al.*⁸⁰

Despite a reference to 21 papers, Truman *et al.*⁸⁰ based their conclusion of CWF effectiveness on 14 studies grouped into three groups:

- Studies starting or continuing CWF with before and after measurements (Group A-On)
- Studies stopping CWF with before and after measurements (Group A-Off)
- Studies starting or continuing CWF with only post measurements (Group B-On)

They calculated a number of “estimates of effectiveness” using two formulas:

Group A (before-and-after):

$$\{(NoF_{pre} - NoF_{post}) - (F_{pre} - F_{post})\} / NoF_{pre}$$

Group B (post measurements only):

$$(F_{post} - NoF_{post}) / NoF_{post}$$

The measures were mostly DMFT or dft. See Table 5 for summaries.

The median of the estimates thus calculated for each group was taken to represent the CWF effectiveness for each type of studies, even though median can be sensitive to the studies or estimates included in the set. The results were 29.1% for Group A-On (based on 21 estimates from 7 studies), 50.7% for Group B-On (based on 20 estimates from 7 studies), and 17.9% for Group A-Off (based on 5 estimates from 3 studies). With these numbers the authors concluded that “strong evidence shows that CWF is effective.” Below, we discuss a number of problems.

Selection of studies: Of the 14 studies, only one 1956 article is a U.S. study.⁹³ The two large-scale,

multimillion dollar NIDR surveys were not included, peculiar as this review was to be the basis for setting goals for U.S. public policies. Szpunar and Burt,⁴⁹ a study co-authored by the organizer of the 1989 Michigan Workshop, was not included, nor was Shiboski *et al.*,¹²¹ a CDC-funded study examining caries in California children by ethnicity and head-start (or low income) status. One would expect the authors of Truman *et al.*⁸⁰ to make particular efforts to include this study because (1) the Pacific Region was the least fluoridated region and hence the main target of a new push for CWF and (2) they posed “What is the effectiveness of CWF in reducing socioeconomic or racial and ethnic disparities in caries burden?” as an important unanswered question.

Among the included studies, Loh⁹⁶ is a review article providing partial information from a 1970 paper; it failed to meet the authors’ stated criteria for inclusion. Another inappropriate inclusion was Hawew *et al.*,¹⁰³ a Libyan study with the goals of demonstrating feasibility of collecting data and recording the caries prevalence in Benghazi (0.8 mg/l). The paper also reports data for a small rural area with 1.8 mg/l fluoride concentration, but the comparison of 0.8 (within the CWF range of 0.7–1.2 mg/l) versus 1.8 mg/l (above the CWF range) is not relevant to demonstrating the effectiveness of CWF.

Some authors of the included studies have published other CWF studies, e.g. Attwood co-authored Downer *et al.*,¹⁵⁰ which could be a B-On study. Künzel *et al.*¹⁵¹ and the many studies cited therein could be in group A-Off. These omissions are particularly surprising since group A-Off has only three studies and five estimates.

Selection of estimates: Group A-Off contains three studies and five imputed estimates: 17.9% from Attwood and Blinkhorn,⁹⁹ 29.1% and 31.7% from Kalsbeek *et al.*,¹⁰⁰ and –1.1% and –42.2% from Künzel and Fischer.⁹⁸ Thus the median is 17.9%.

Kalsbeek *et al.*¹⁰⁰ reported measurements for 15-year-olds taken in different years. Of the two before-and-after estimates imputed from this study, one was not a before-and-after comparison — the fluoridated town had stopped CWF about 6 or 7 years before the “before” point.

Künzel and Fischer⁹⁸ reported measurements for every age from 6 to 15 years. This was a large-scale multiyear study, and the sizes of each age group are significant. But instead of imputing multiple estimates from selected single-age data, as was done with some other studies, all single-age data were ignored, and only two age-range summaries were used to impute two estimates. Had Truman *et al.*⁸⁰ been consistent in the selection of estimates, the median for Group A-Off would have shifted to a negative value and changed the conclusion to no CWF effectiveness.

In contrast, four estimates were imputed from the much smaller Libyan study¹⁰³ — for each of the two ages reported, the public school data from the rural town were used twice to impute two estimates by comparing them with the public school data and, separately, with the private school data from Benghazi.

Selection of formula: Within the limited set of studies and estimates selected, the authors failed to apply their formula consistently. Two estimates for deciduous teeth from Guo *et al.*⁷⁶ were included in group A-On and two for permanent teeth in group B-On. The study clearly belongs to group A-On, as it reported before-and-after measurements for all ages and for both deciduous and permanent teeth. Instead of following their stated method and including the estimates of 300%, 211%, and 208% for the permanent teeth of the three selected age groups, they ignored the before measurements and treated them as if there were only post measurements for permanent teeth. Similarly, Evans *et al.*⁹⁷ reported measurements for 5-year-olds divided into three social classes. Truman *et al.*⁸⁰ included three Group A-On estimates, one for each social class; but the combined total for all social groups was treated as a post-only study and contributed another estimate in Group B-On.

The results from the application of the formula can be misleading. For example, the three positive estimates^{99,100} in group A-Off are presented as estimates of how much CWF prevents caries. In fact, the data in these two studies, as well as other studies involving cessation of CWF, showed that there were no increases in caries after stopping fluoridation, aside from possibly a temporary and small increase shortly afterward, which could simply be reflecting the removal of the delayed eruption effect. (Within the 6-year period in Attwood and Blinkhorn,⁹⁹ the mean DMFT decreased by 0.54 in the never-fluoridated town and increased by 0.06 in the town that stopped fluoridation at the midpoint of the period. In the 9-year period that sandwiched the cessation of CWF in Kalsbeek *et al.*,¹⁰⁰ the DMFT decreased by 3.7 in the never-fluoridated town and increased by 0.4 in the fluoridated town; 8 years later, it further decreased by 5.6 in the former and decreased by 2.3 in the latter town.) Thus the purported positive outcomes were purely an artifact of the formula — the never-fluoridated communities had a dramatic reduction in caries without the help of CWF.

THE WORLD-WIDE MOVEMENT AGAINST WATER FLUORIDATION

In stark contrast to the Center for Disease Control's claim that fluoridation is one of the top ten public health achievements of the 20th century, it is **one of the most widely rejected health interventions in the world.**

Out of 196 nations, only 24 have any fluoridation, and only 10, like the U.S., for more than half their population. Over 95% of the world's population is fluoridation-free. The U.S. fluoridates as many people as the rest of the world combined.

None of the largest Asian nations, including China, India and Japan, fluoridate. Out of 54 countries in Africa, only one fluoridates – Libya, and only for a small percent of its population. In Europe, only four out of 48 countries fluoridate (less than 2% of the population). A few have fluoridated salt, but only as a consumer choice.

France, Germany, Belgium, the Netherlands, Denmark, Norway and Sweden have all prohibited fluoridation, many citing the ethical problem of putting any drug in drinking water.

For dozens of nations that haven't banned it, thousands of major cities and smaller towns don't fluoridate, including **Athens, Barcelona, Budapest, Geneva, Helsinki, London, Madrid, Prague, Rome, Vienna and Warsaw**. Ireland is the only European nation mandating fluoridation. But despite the mandate, 13 town and county councils, including Dublin and Cork, have voted for its immediate cessation.

Many organizations still support fluoridation, but **those opposing it grows year by year**. They include:

- American Academy of Environmental Medicine • Center for Health, Environment and Justice
- Children's Health Defense • Eau Secours (Canadian coalition of 234 groups promoting clean, safe water)
- Council of Canadians • Environmental Working Group • Food and Water Watch
- * Institute of Neurotoxicology & Neurological Disorders • International Academy of Biological Dentistry and Medicine
- International Academy of Oral Medicine and Toxicology • League of United Latin American Citizens
- Moms Against Fluoridation • Organic Consumers Association

In addition, **many organizations once endorsing fluoridation have pulled back**, no longer taking a position. They include the Alzheimer's Association, American Academy of Allergy, Asthma and Immunology, Center for Science in the Public Interest, Consumers Union (Consumer Reports), National Association of Social Workers, National Down Syndrome Congress, National Down Syndrome Society and National Kidney Foundation.

The trend is clear. And as the scientific data accumulate, more and more nations, cities and organizations are challenging the safety, efficacy, costs and ethics of fluoridation.

National Toxicology Program

U.S. Department of Health and Human Services

DRAFT NTP MONOGRAPH ON THE SYSTEMATIC REVIEW OF FLUORIDE EXPOSURE AND NEURODEVELOPMENTAL AND COGNITIVE HEALTH EFFECTS*

Revised September 16, 2020

*The September 6, 2019 draft monograph was peer reviewed by a committee convened by the National Academy of Sciences, Engineering, and Medicine (NASEM). This current draft incorporates changes in response to that review and is being submitted to the same NASEM committee for an additional round of peer review.

Office of Health Assessment and Translation
Division of the National Toxicology Program
National Institute of Environmental Health Sciences
National Institutes of Health

U.S. DEPARTMENT OF HEALTH AND HUMAN SERVICES

NOTICE:

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review under the applicable information quality guidelines. It has not been formally disseminated by NTP. It does not represent and should not be construed to represent any NTP determination or policy.

FOREWORD

The National Toxicology Program (NTP), established in 1978, is an interagency program within the Public Health Service of the U.S. Department of Health and Human Services. Its activities are executed through a partnership of the National Institute for Occupational Safety and Health (part of the Centers for Disease Control and Prevention), the Food and Drug Administration (primarily at the National Center for Toxicological Research), and the National Institute of Environmental Health Sciences (part of the National Institutes of Health), where the program is administratively located. NTP offers a unique venue for the testing, research, and analysis of agents of concern to identify toxic and biological effects, provide information that strengthens the science base, and inform decisions by health regulatory and research agencies to safeguard public health. NTP also works to develop and apply new and improved methods and approaches that advance toxicology and better assess health effects from environmental exposures.

NTP conducts literature-based evaluations to determine whether exposure to environmental substances (e.g., chemicals, physical agents, and mixtures) may be associated with adverse health effects. These evaluations result in hazard conclusions or characterize the extent of the evidence and are published in the NTP Monograph series, which began in 2011. NTP Monographs serve as an environmental health resource to provide information that can be used to make informed decisions about whether exposure to a substance may be of concern for human health.

NTP conducts these health effects evaluations following pre-specified protocols that apply the general methods outlined in the [“Handbook for Conducting a Literature-Based Health Assessment Using the OHAT Approach for Systematic Review and Evidence Integration.”](#)¹ The protocol describes project-specific procedures tailored to each systematic review in a process that facilitates evaluation and integration of scientific evidence from published human, experimental animal, and mechanistic studies.

The key feature of the systematic review approach is the application of a transparent framework to document the evaluation methods and the basis for scientific judgements. This process includes steps to comprehensively search for studies, select relevant evidence, assess individual study quality, rate confidence in bodies of evidence across studies, and then integrate evidence to develop conclusions for the specific research question. Draft monographs undergo external peer review prior to being finalized and published.

NTP Monographs are available free of charge on the [NTP website](#) and cataloged in [PubMed](#), a free resource developed and maintained by the National Library of Medicine (part of the National Institutes of Health). Data for these evaluations are included in the [Health Assessment and Workspace Collaborative](#).

For questions about the monographs, please email [NTP](#) or call 984-287-3211.

¹ OHAT is the abbreviation for Office of Health Assessment and Translation, which is within the Division of the National Toxicology Program at the National Institute of Environmental Health Sciences.

TABLE OF CONTENTS

Foreword.....	ii
Table of Contents.....	iii
List of Tables and Figures	v
Abstract.....	1
Introduction	3
Objective and Specific Aims.....	4
Objective	4
Specific Aims	5
Methods.....	5
Problem Formulation and Protocol Development.....	5
NASEM Review	6
PECO Statements	6
Literature Search.....	8
Main Literature Search.....	8

ABSTRACT

Background: The overall objective of this evaluation was to undertake a systematic review of published literature to reach conclusions concerning the potential for exposure to fluoride to affect neurodevelopment and cognition. The review only addresses whether exposure to fluoride could present a potential hazard (i.e., has the potential to cause harm, at any exposure level, including exposures that are higher than those typically encountered from consuming fluoridated drinking water in the United States). Benefits of fluoride with respect to oral health are not addressed in this monograph.

Previous reviews of epidemiological studies, including a 2006 evaluation by the National Research Council (NRC), found support for an association between consumption of high levels of naturally occurring fluoride in drinking water and adverse neurological effects in humans and recommended further investigation (NRC 2006). Most of the evidence reviewed was from dental and skeletal fluorosis-endemic regions that have higher levels of naturally occurring fluoride than the fluoride concentrations historically added to water in community water fluoridation programs (0.8–1.2 mg/L). For community water systems that add fluoride, the Public Health Service now recommends a fluoride concentration of 0.7 mg/L.

NTP previously published a systematic review of the evidence from experimental animal studies of the effects of fluoride on learning and memory (NTP 2016). The systematic review found a low-to-moderate level of evidence that learning and memory deficits occur in non-human mammals exposed to fluoride. Studies in animals generally used fluoride drinking water concentrations that far exceeded the levels used in water fluoridation, and the lack of studies at lower fluoride concentrations was identified as a data gap. The evidence for effects on learning and memory was strongest (moderate) in animals exposed as adults, and evidence was weaker (low) in animals exposed during development. Since the publication of the NTP (2016) systematic review of the animal evidence, additional animal studies have been published, many examining the effects of perinatal exposures. In addition, the number of studies examining cognitive and neurobehavioral effects of fluoride in humans has grown considerably since the NRC (2006) review, including several recent prospective cohort studies evaluating prenatal fluoride exposures.

Objective: To conduct a systematic review of the human, experimental animal [extending (NTP 2016) report], and mechanistic literature to evaluate the evidence and develop hazard conclusions about whether fluoride exposure is associated with neurodevelopmental and cognitive effects.

Method: A systematic review protocol was developed and utilized following the Office of Health Assessment and Translation (OHAT) approach for conducting literature-based health assessments.

Results: The literature search and screening process identified 159 published human studies, 339 published experimental animal studies, and 60 in vitro/mechanistic studies relevant to the objective. Ninety-two of the 159 human studies evaluated the association between fluoride exposure and neurodevelopmental or cognitive effects, and the remaining human studies evaluated thyroid effects or other potential mechanistic data. The majority of the experimental animal studies were mechanistic studies, which were not assessed in the NTP (2016) report. Since the NTP (2016) systematic review (through April 2019), 35 experimental animal studies evaluating effects on learning and memory and/or motor activity and sensory effects of fluoride were identified.

Supported by a meta-analysis, the human body of evidence provides a consistent and robust pattern of findings that higher fluoride exposure (e.g., >1.5 mg/L in drinking water) is associated with adverse effects on neurocognitive development, including lower intelligence quotient (IQ) in children. There is a moderate level of evidence from cognitive neurodevelopmental studies in children based on five prospective cohort studies and 14 cross-sectional studies where exposure was identified as occurring prior to outcome. The evidence for cognitive effects in adults is limited, coming from two cross-sectional studies, and is inadequate to evaluate whether fluoride exposure in adults is associated with cognitive effects. The assessment of the new animal data focuses on evaluating a deficiency identified during the prior NTP (2016) review concerning the difficulty in distinguishing potential effects of fluoride on motor and sensory functions from effects specifically on learning and memory functions. Further examination of the animal data, including studies carried out at the NTP, has not resolved this issue. Because of this and other deficiencies related to overall study quality, the animal body of evidence is now considered inadequate to inform conclusions on whether fluoride exposure is associated with cognitive effects (including cognitive neurodevelopmental effects) in humans. While the animal data provide evidence of effects of fluoride on neurodevelopment, the human evidence base is primarily focused on cognitive neurodevelopmental effects, and these human data are the primary basis of conclusions.

Conclusions: Because the majority of available studies evaluated cognitive neurodevelopmental effects in children, the focus of the hazard conclusions is on cognitive neurodevelopmental effects, primarily IQ. When focusing on findings from studies with exposures in ranges typically found in drinking water in the United States (0.7 mg/L for optimally fluoridated community water systems)² that can be evaluated for dose response, effects on cognitive neurodevelopment are inconsistent, and therefore unclear. However, when considering all the evidence, including studies with exposures to fluoride levels higher than 1.5 mg/L in water, NTP concludes that fluoride is *presumed to be a cognitive neurodevelopmental hazard to humans*. This conclusion is based on a moderate level of evidence that shows a consistent and robust pattern of findings in human studies across several different populations demonstrating that higher fluoride exposure (e.g., >1.5 mg/L in drinking water) is associated with lower IQ and other cognitive effects in children. Limited and weaker evidence is considered to provide an inadequate level of evidence that fluoride is associated with cognitive effects in adults. The evidence from animal studies is inadequate to inform conclusions on cognitive effects, and the mechanisms underlying fluoride-associated cognitive neurodevelopmental effects are not well characterized.

²As of April 2020, 1.08% of persons living in the United States (~ 3.5 million people) were served by community water systems (CWS) containing ≥ 1.1 mg/L naturally occurring fluoride. CWS supplying water with ≥ 1.5 mg/L naturally occurring fluoride served 0.59% of the U.S. population (~ 1.9 million people), and systems supplying water with ≥ 2 mg/L naturally occurring fluoride served 0.31% of the U.S. population (~1 million people) (<https://www.cdc.gov/fluoridation/data-tools/reporting-system.html>).

INTRODUCTION

The NTP's Office of Health Assessment and Translation (OHAT) conducted a systematic review to evaluate the evidence that exposure to fluoride is associated with neurodevelopmental or cognitive effects. This review was initiated in response to a nomination from the Fluoride Action Network. There are numerous human and animal studies reporting neurodevelopmental and cognitive health effects of exposure to excess fluoride. As noted by the National Research Council (NRC) in their 2006 report, although the studies lacked sufficient detail to fully assess their quality and relevance to the U.S. populations, the consistency of the results suggesting that fluoride may be neurotoxic warrants additional research (NRC 2006).

Fluoride salts are added to community water systems and dental products in the United States (e.g., toothpaste, mouth rinses, and supplements) for the prevention of dental caries. Approximately 67% of the U.S. population receives fluoridated water through a community drinking water system (CDC 2013). In other countries fluoride supplementation has been achieved by fluoridating food products such as salt, or milk. Fluoride supplementation has been recommended to prevent bone fractures (Jones *et al.* 2005). Fluoride also can occur naturally in drinking water. Other sources of human exposure include other foods and beverages, industrial emissions, pharmaceuticals, and pesticides (e.g., cryolite, sulfuryl fluoride). Soil ingestion is another source of fluoride exposure in young children (US EPA 2010).

The U.S. Public Health Service (PHS) first recommended communities add fluoride to drinking water in 1962. PHS guidance is advisory, not regulatory, which means that while PHS recommends community water fluoridation as a public health intervention, the decision to fluoridate water systems is made by state and local governments.³ For community water systems that add fluoride, PHS now recommends a fluoride concentration of 0.7 milligrams/liter (mg/L) (equal to 0.7 parts per million [ppm]). Under the Safe Drinking Water Act, the U.S. Environmental Protection Agency (EPA) sets maximum exposure level standards for drinking water quality. The current enforceable drinking water standard for fluoride, or the maximum contaminant level goal (MCLG, a concentration at which no adverse health effects are expected), is 4.0 mg/L. This is the maximum amount of fluoride contamination (naturally occurring not from water fluoridation) that is allowed in water from public water systems; it is set to protect against increased risk of skeletal fluorosis, a condition characterized by pain and tenderness of the major joints. EPA also has a non-enforceable secondary drinking water standard of 2.0 mg/L, which is recommended to protect children against the tooth discoloration and/or pitting that can be caused by severe dental fluorosis during the formative period prior to eruption of the teeth. Although the secondary standard is not enforceable, EPA does require that public water systems notify the public if the average levels exceed it (NRC 2006). As of April 2020, 1.08% of persons living in the United States (~ 3.5 million people) were served by community water systems (CWS) containing ≥ 1.1 mg/L naturally occurring fluoride. CWS supplying water with ≥ 1.5 mg/L naturally occurring fluoride served 0.59% of the U.S. population (~ 1.9 million people), and systems supplying water with ≥ 2 mg/L naturally occurring fluoride served 0.31% of the U.S. population (~1 million people) (<https://www.cdc.gov/fluoridation/data-tools/reporting-system.html>).

Controversy over community water fluoridation stems from concerns about the potential harmful effects of fluoride and the ethics of water fluoridation. Commonly cited health concerns related to

³ For many years, most fluoridated community water systems used fluoride concentrations ranging from 0.8 to 1.2 mg/L (US DHHS 2015).

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

fluoride are bone fractures and skeletal fluorosis, lower intelligence quotient (IQ) and other neurological effects, cancer, and endocrine disruption. Effects on neurological function, endocrine function (e.g., thyroid, parathyroid, pineal), metabolic function (e.g., glucose metabolism), and carcinogenicity were assessed in the 2006 NRC report *Fluoride in Drinking Water: A Scientific Review of EPA's Standards* (NRC 2006). The NRC review considered adverse effects of water fluoride, focusing on a range of concentrations (2–4 mg/L) above the current 0.7-mg/L recommendation for community water fluoridation (NRC 2006). The NRC report concluded that the current MCLG should be lowered to protect against severe enamel fluorosis and to reduce the risk of bone fractures associated with skeletal fluorosis (NRC 2006). Other than severe fluorosis, the NRC did not find sufficient evidence of negative health effects at fluoride levels below 4.0 mg/L; however, the NRC concluded that the consistency of the results of IQ deficits in children exposed to fluoride at 2.5 to 4 mg/L in drinking water from a few epidemiological studies of Chinese populations appeared significant enough to warrant additional research on the effects of fluoride on intelligence. The NRC report noted several challenges to evaluating the literature, citing deficiencies in reporting quality, lack of consideration of all sources of fluoride exposure, incomplete consideration of potential confounding, selection of inappropriate control subject populations in epidemiological studies, absence of demonstrated clinical significance of reported endocrine effects, and incomplete understanding of the biological relationship between histological, biochemical, and molecular alterations with behavioral effects (NRC 2006).

In 2016, NTP conducted a systematic review of the evidence from experimental animal studies on the potential effects of fluoride exposure on learning and memory (NTP 2016). The NTP (2016) systematic review found a low-to-moderate level of evidence that learning and memory deficits occur in experimental animals exposed to fluoride. Based on the findings in NTP (2016), NTP decided to conduct additional animal studies before carrying out a full systematic review to incorporate human, animal, and potentially relevant mechanistic evidence in order to reach hazard identification conclusions for fluoride and learning and memory effects. As the NTP (2016) report on the experimental animal evidence focused on learning and memory and developed confidence ratings for bodies of evidence by life stage of exposure (i.e., exposure during development or adulthood), this report also evaluates two different age groups in humans (i.e., children and adults) with a focus on cognitive neurodevelopmental effects in children and cognitive effects in adults in order to address potential differences in the health impact based on timeframe of exposure (i.e., during development or during adulthood). This evaluation has been conducted separately from the 2016 experimental animal assessment, but like the 2016 assessment, it has assessed mainly learning and memory effects in experimental animal studies to determine whether the findings inform the assessment of cognitive neurodevelopmental effects in children and cognitive effects in adults. The September 6, 2019 draft of this monograph was reviewed by a committee convened by the National Academy of Sciences, Engineering, and Medicine (NASEM). The current document incorporates changes in response to that review.

OBJECTIVE AND SPECIFIC AIMS

Objective

The overall objective of this evaluation is to undertake a systematic review to develop NTP hazard identification conclusions on the association between exposure to fluoride and neurodevelopmental and cognitive effects based on integrating levels of evidence from human and non-human animal studies with consideration of the degree of support from mechanistic data.

Specific Aims

- Identify literature that assessed neurodevelopmental and cognitive health effects, especially outcomes related to learning, memory, and intelligence, following exposure to fluoride in human, animal, and relevant in vitro/mechanistic studies.
- Extract data on potential neurodevelopmental and cognitive health effects from relevant studies.
- Assess the internal validity (risk of bias) of individual studies using pre-defined criteria.
- Assess effects on thyroid function to help evaluate potential mechanisms of impaired neurological function.
- Summarize the extent and types of health effects evidence available.
- Describe limitations of the systematic review, limitations of the evidence base, identify areas of uncertainty, as well as data gaps and research needs for neurodevelopmental and cognitive health effects of fluoride.

Dependent on the extent and nature of the available evidence:

- Synthesize the evidence using a narrative approach or meta-analysis (if appropriate) considering limitations on data integration such as study design heterogeneity.
- Rate confidence in the body of evidence for human and animal studies separately according to one of four statements: High, Moderate, Low, or Very Low/No Evidence Available.
- Translate confidence ratings into level of evidence of health effects for human and animal studies separately according to one of four statements: High, Moderate, Low, or Inadequate.
- Combine the level of evidence ratings for human and animal data to reach one of five possible hazard identification conclusions: Known, Presumed, Suspected, Not classifiable, or Not identified to be a hazard to humans.

METHODS

Problem Formulation and Protocol Development

The research question and specific aims stated above were developed and refined through a series of problem formulation steps including:

- (1) receipt of nomination from the public in June 2015 to conduct analyses of fluoride and developmental neurobehavioral toxicity;
- (2) analysis of the extent of evidence available and the merit of pursuing systematic reviews, given factors such as the extent of new research published since previous evaluations and whether these new reports address or correct the deficiencies noted in the literature (NRC 2006, OEHHA 2011, SCHER 2011);
- (3) request for information in a Federal Register notice (dated October 7, 2015);
- (4) consideration of comments providing a list of studies to review through Federal Register notice and public comment period from October 7, 2015 to November 6, 2015;

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

- (5) release of draft concept titled *Proposed NTP Evaluation on Fluoride Exposure and Potential for Developmental Neurobehavioral Effects* in November 2015;
- (6) presentation of draft concept at the NTP Board of Scientific Counselors (BSC) meeting on December 1–2, 2015;
- (7) consideration of comments on NTP’s draft concept from the NTP BSC meeting in December 2015; and
- (8) consideration of input on the draft protocol from review by technical advisors.

NTP published a systematic review of the animal evidence on the effects of fluoride on learning and memory (NTP 2016). NTP has conducted additional studies in animals to assess the effect of fluoride exposure on learning and memory. The results from this experimental animal work were published (McPherson *et al.* 2018) and are incorporated into the current review, which considers the epidemiological, animal, and mechanistic evidence in its conclusions. The protocol used to conduct this systematic review was posted in June 2017 with updates posted in May 2019 and September 2020 (<https://ntp.niehs.nih.gov/go/785076>).⁴ A brief summary of the methods is presented below.

NASEM Review

The September 6, 2019 draft of this monograph was peer reviewed by a committee convened by NASEM. The current draft reflects clarifications and changes in response to that review (NASEM 2020), including the addition of meta-analyses of the IQ studies in children.

PECO Statements

PECO (Population, Exposure, Comparators and Outcomes) statements were developed as an aid to identify search terms and inclusion/exclusion criteria as appropriate for addressing the overall research question (effects on neurodevelopmental or cognitive function and thyroid associated with fluoride exposure) for the systematic review (Higgins and Green 2011). The PECO statements are listed below for human, animal, and in vitro/mechanistic studies (see [Table 1](#), [Table 2](#), and [Table 3](#)).

Using the PECO statements, the evaluation searched for evidence of neurodevelopmental or cognitive function, and thyroid effects associated with fluoride exposure from human studies, controlled exposure animal studies, and mechanistic/in vitro studies. Mechanistic data can come from a wide variety of studies that are not intended to identify a disease phenotype. This source of experimental data includes in vitro and in vivo laboratory studies directed at cellular, biochemical, and molecular mechanisms that attempt to explain how a substance produces particular adverse health effects. The mechanistic data were first organized by general categories (e.g., biochemical effects in the brain and neurons, neurotransmitters, oxidative stress, etc.) to evaluate the information available. Categories focused on were those with more robust data at levels of fluoride more relevant to human exposure. The intent was not to develop a mechanism for fluoride induction of learning and memory effects, but to evaluate whether a plausible series of mechanistic events exists to support effects observed in the low-dose

⁴ NTP conducts systematic reviews following pre-specified protocols that describe the review procedures selected and applied from the general methods outlined in the OHAT Handbook for Conducting a Literature-Based Health Assessment (<http://ntp.niehs.nih.gov/go/38673>). The protocol describes project-specific procedures tailored to each systematic review.

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

region (below approximate drinking water equivalent concentrations of 20 ppm) that may strengthen the hazard conclusion.

Table 1. Human PECO (Population, Exposure, Comparator and Outcome) Statement	
PECO Element	Evidence
Population	Humans without restriction as to age or sex, geographic location, or life stage at exposure or outcome assessment
Exposure	Exposure to fluoride based on administered dose or concentration, biomonitoring data (e.g., urine, blood, other specimens), environmental measures (e.g., air, water levels), or job title or residence. Relevant forms are those used as additives for water fluoridation: • Fluorosilicic acid (also called hydrofluorosilicate; CASRN 16961-83-4) • Sodium hexafluorosilicate (also called disodium hexafluorosilicate or sodium fluorosilicate; CASRN 16893-85-9) • Sodium fluoride (CASRN 7681-49-4) • Other forms of fluoride that readily dissociate into free fluoride ions (e.g., potassium fluoride, calcium fluoride, ammonium fluoride)
Comparators	Comparable populations not exposed to fluoride or exposed to lower levels of fluoride (e.g., exposure below detection levels)
Outcomes	Neurodevelopmental outcomes including learning, memory, intelligence, other forms of cognitive behavior, other neurological outcomes (e.g., anxiety, aggression, motor activity), and biochemical changes in the brain or nervous system tissue; or measures of thyroid function, biochemical changes, or thyroid tissue

Table 2. Animal PECO Statement	
PECO Element	Evidence
Population	Non-human mammalian animal species (whole organism)
Exposure	Exposure to fluoride based on administered dose or concentration, and biomonitoring data (e.g., urine, blood, other specimens). Relevant forms are those used as additives for water fluoridation: • Fluorosilicic acid (also called hydrofluorosilicate; CASRN 16961-83-4) • Sodium hexafluorosilicate (also called disodium hexafluorosilicate or sodium fluorosilicate; CASRN 16893-85-9) • Sodium fluoride (CASRN 7681-49-4) • Other forms of fluoride that readily dissociate into free fluoride ions (e.g., potassium fluoride, calcium fluoride, ammonium fluoride)
Comparators	Comparable animals that were untreated or exposed to vehicle-only treatment
Outcomes	Neurodevelopmental outcomes including learning, memory, intelligence, other forms of cognitive behavior, other neurological outcomes (e.g., anxiety, aggression, motor activity), and biochemical changes in the brain or nervous system tissue; or measures of thyroid function, biochemical changes, or thyroid tissue

Table 3. In Vitro/Mechanistic PECO Statement	
PECO Element	Evidence
Population	Human or animal cells, tissues, or biochemical reactions (e.g., ligand binding assays)
Exposure	Exposure to fluoride based on administered dose or concentration. Relevant forms are those used as additives for water fluoridation: • Fluorosilicic acid (also called hydrofluorosilicate; CASRN 16961-83-4) • Sodium hexafluorosilicate (also called disodium hexafluorosilicate or sodium fluorosilicate; CASRN 16893-85-9) • Sodium fluoride (CASRN 7681-49-4) • Other forms of fluoride that readily dissociate into free fluoride ions (e.g., potassium fluoride, calcium fluoride, ammonium fluoride)
Comparators	Comparable cells or tissues that were untreated or exposed to vehicle-only treatment
Outcomes	Endpoints related to neurological and thyroid function, including neuronal electrophysiology; mRNA, gene, or protein expression; cell proliferation or death in brain or thyroid tissue/cells; neuronal signaling; synaptogenesis, etc.

Literature Search

Main Literature Search

Search terms were developed to identify all relevant published evidence on developmental neurobehavioral toxicity or thyroid-related health effects potentially associated with exposure to fluoride by reviewing Medical Subject Headings for relevant and appropriate neurobehavioral and thyroid-related terms, and by extracting key neurological and thyroid-related health effects and

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

developmental neurobehavioral terminology from reviews and a sample of relevant primary data studies. A combination of relevant subject headings and keywords were subsequently identified. A test set of relevant studies was used to ensure the search terms retrieve 100% of the test set. Six electronic databases were searched (see [Main Literature Database Search](#)) using a search strategy tailored for each database (specific search terms used for the PubMed search are presented in [Appendix 1](#); the search strategy for other databases are available in the protocol (<https://ntp.niehs.nih.gov/go/785076>)). A search of PubChem indicated that sodium fluoride was not found in either the Tox21 or ToxCast databases; therefore, these databases were not included in the search. No language restrictions or publication year limits were imposed. These six databases were searched in December 2016 and the search was regularly updated during the review process through April 1, 2019.

Evaluations must include cut-off dates for the literature search to enable synthesis and development of conclusions. Following the NASEM committee peer review in November 2019 (NASEM 2020), an additional search was conducted on May 1, 2020, where only primary human epidemiology studies were prioritized during screening. The review of the 2020 search results focused on the human studies because they formed the basis of the conclusions in the September 6, 2019 draft. A supplemental literature search of Chinese-language databases (described below) was also conducted.

Publications identified in these searches are categorized as “references identified through database searches” in [Figure 4](#). Studies identified from other sources or manual review that might impact conclusions were considered under “references identified through other sources” in [Figure 4](#). Literature searches for this systematic review were conducted independently from the literature search conducted for NTP (2016). The current literature search strategy was based on the search terms used for NTP (2016) and refined for the current evaluation, including the addition of search terms to identify human studies. Although the review process identified studies prior to 2015, the current assessment did not evaluate the studies published prior to 2015 and relied on the NTP (2016) assessment. The focus of the literature searches for this systematic review was to identify and evaluate relevant animal studies that were published since completion of the literature searches for the NTP (2016) assessment in addition to the human and mechanistic data that were not previously evaluated.

Supplemental Chinese Database Literature Search

Following NASEM committee peer review in November 2019 (NASEM 2020), additional searches were developed for non-English-language databases to systematically search for studies that were previously identified from other resources (e.g., Chinese-language studies from the Fluoride Action Network website). Non-English-language databases with the greatest potential to contain relevant non-English publications that were not previously identified through database searches were selected. Multiple non-English language databases were explored before finding two databases (CNKI and Wanfang) that covered studies previously identified from other sources. These two Chinese electronic databases were searched in May 2020 with no language restrictions or publication year limits. Search terms from the main literature search were refined to focus on human epidemiology studies. The CNKI and Wanfang databases have character limits in the search strings; therefore, key terms were prioritized using text analytics to identify the most prevalent terms from neurodevelopmental or cognitive human epidemiology studies previously identified as relevant. Search strings were designed to capture known relevant studies that were previously identified from searching other resources without identifying large numbers of non-relevant studies [the search strategy for both databases are available in the protocol (<https://ntp.niehs.nih.gov/go/785076>)]. Publications retrieved were compared to publications retrieved from the main literature search and duplicates were removed. The remaining relevant publications are categorized as “references identified through database searches” in [Figure 4](#). New animal and

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

mechanistic references retrieved were scanned for evidence that might extend the information currently in the September 6, 2019 draft. Although additional studies were identified, data that would materially advance the animal and mechanistic findings were not identified; therefore, these studies were not extracted nor were they added to the draft. Newly-retrieved human references were reviewed to identify studies that might impact conclusions with priority given to identifying and translating null studies that may have been missed using previous approaches. Null studies that were identified were translated and included.

Supplemental Chinese Database Literature Search

- CNKI
- Wanfang

Searching Other Resources

The reference lists of all included studies; relevant reviews, editorials and commentaries; and the Fluoride Action Network website (<http://fluoridealert.org/>) were manually searched for additional relevant publications. Following NASEM committee peer review in November 2019 (NASEM 2020), the Fluoride Action Network website was again searched for relevant references and contacted to identify null or no effect studies.

Unpublished Data

Unpublished data were eligible for inclusion provided the owner of the data was willing to have the data made public and peer reviewed (see protocol for more details <https://ntp.niehs.nih.gov/go/785076>). No unpublished data were identified during the literature search.

Study Selection

Evidence Selection Criteria

In order to be eligible for inclusion, studies had to satisfy eligibility criteria that reflect the PECO statement in [Table 1](#), [Table 2](#), and [Table 3](#). The following additional exclusion criteria were applied (see protocol for additional details; <https://ntp.niehs.nih.gov/go/785076>):

- (1) Case studies and case reports.
- (2) Articles without original data (e.g., reviews, editorials, or commentaries). Reference lists from these materials, however, were reviewed to identify potentially relevant studies not identified from the database searches. New studies identified were assessed for eligibility for inclusion.
- (3) Conference abstracts or reports.

Screening Process

References retrieved from the literature search were independently screened by two trained screeners at the title and abstract level to determine whether a reference met the evidence selection criteria. Screening procedures following the evidence selection criteria in the protocol were pilot-tested with experienced contract staff overseen by NTP. For citations with no abstract or non-English abstracts, articles were screened based on title relevance (title would need to indicate clear relevance); number of pages (articles ≤ 2 pages were assumed to be conference reports, editorials, or letters unlikely to contain original data); and/or PubMed Medical Subject Headings (MeSH). Using this approach, literature was manually screened for relevance and eligibility against the evidence selection criteria using a structured form in SWIFT-Active Screener. While the human screeners review studies, SWIFT-Active Screener aids in the process by employing a machine-learning software program used to priority-rank studies for screening (Howard *et al.* 2020). SWIFT-Active Screener also refines a statistical model that continually ranks the remaining studies according to their likelihood for inclusion. In addition, SWIFT-Active Screener employs active learning to continually incorporate user feedback during title and abstract screening to predict the total number of included studies, thus providing a statistical basis for a decision about when to stop screening (Miller *et al.* 2016). Title and abstract screening was stopped once the statistical algorithm in SWIFT-Active Screener estimated that 98% of the predicted number of relevant studies were identified.

Studies that were not excluded during the title and abstract screening were further screened for inclusion with a full-text review by two independent reviewers using [DistillerSR®](#) by Evidence Partners, a web-based, systematic-review software program with structured forms and procedures to ensure standardization of the process. Screening conflicts were resolved through discussion and consultation with technical advisor(s), if necessary. During full-text review, studies that were considered relevant were tagged to the appropriate evidence streams (i.e., human, animal, and/or in vitro). Studies tagged to human or animal evidence streams were also categorized by outcome as primary neurodevelopmental or cognitive outcomes (learning, memory, and intelligence); secondary neurobehavioral outcomes (anxiety, aggression, motor activity, or biochemical); or related to thyroid effects. In vitro data were tagged as being related to neurological effects or thyroid effects. Translation assistance was sought to assess the relevance of non-English studies. Following full-text review, the remaining studies were “included” and used for the evaluation.

Screening of the May 2020 Literature Search Update

Following the NASEM committee peer review in November 2019 (NASEM 2020), an additional search was conducted on May 1, 2020, where only primary human epidemiology studies were identified. The study screening and selection process was focused on the human studies with primary outcomes for the evaluation because they form the basis of the conclusions. Animal in vivo, human secondary outcome-only, and human and animal mechanistic references were identified as part of the screening process. These studies were then scanned for evidence that might extend the information in the September 6, 2019 draft. Studies from the May 2020 literature search update will be listed in an appendix; however, data from the studies were not extracted unless it was believed they would materially advance the findings.

Data Extraction

Data were collected (i.e., extracted) from included studies by one member of the evaluation team and checked by a second member of the team for completeness and accuracy. Any discrepancies in data extraction were resolved by discussion or consultation with a third member of the evaluation team.

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

Data extraction was completed using the Health Assessment Workspace Collaborative (HAWC), an open source and freely available web-based interface application.⁵ Data extraction elements are listed separately for human, animal, and in vitro studies in the protocol (<https://ntp.niehs.nih.gov/go/785076>). Data for primary and secondary outcomes as well as thyroid hormone level data were extracted from human studies. Studies evaluating only goiters or thyroid size were not extracted. All primary outcomes and functional neurological secondary outcomes (e.g., motor activity) were extracted from animal studies identified since the NTP (2016) report. For animal mechanistic data, studies were tiered based on exposure dose (with preference given to fluoride drinking water equivalent exposures, which were calculated using the method described in the NTP (2016) report) of 20 ppm or less as deemed most relevant to exposures in humans), exposure duration or relevant time window (i.e., developmental), exposure route (with preference given to oral exposures over injection exposures), and commonality of mechanism (e.g., inflammation, oxidative stress, changes in neurotransmitters, and histopathological changes were considered pockets of mechanistic data). Data were not extracted from in vitro studies; however, these studies were evaluated for biological plausibility of the human and animal results. Thyroid data were also reviewed but not extracted. The data extraction results for included studies are publicly available and can be downloaded in Excel format through HAWC (<https://hawcproject.org/assessment/405/>). Methods for transforming and standardizing dose levels and results from behavioral tests in experimental animals are detailed in the protocol (<https://ntp.niehs.nih.gov/go/785076>).

In 2016, NTP conducted a systematic review of the evidence from experimental animal studies on the potential effects of fluoride exposure on learning and memory (NTP 2016). The literature searches for the current assessment identified and evaluated relevant animal studies published since the 2016 assessment and also included human and mechanistic data that were not previously evaluated. Although literature search activities for the current assessment identified experimental animal studies prior to 2015, the current assessment did not re-evaluate studies published prior to 2015, but relied on the NTP (2016) assessment.

Quality Assessment of Individual Studies

Risk of bias was assessed for individual studies using a tool developed by OHAT that outlines a parallel approach to evaluating risk of bias from human, animal, and mechanistic studies to facilitate consideration of risk of bias across evidence streams with common terms and categories. The risk-of-bias tool is comprised of a common set of 11 questions that are answered based on the specific details of individual studies to develop risk-of-bias ratings for each question. Study design determines the subset of questions used to assess risk of bias for an individual study (see [Table 4](#)).

Assessors were trained with an initial pilot phase undertaken to improve clarity of rating criteria and to improve consistency among assessors. Studies were independently evaluated by two trained assessors who answered all applicable risk-of-bias questions with one of four options in [Table 5](#) following pre-specified criteria detailed in the protocol (<https://ntp.niehs.nih.gov/go/785076>). The criteria describe aspects of study design, conduct, and reporting required to reach risk-of-bias ratings for each question

⁵ HAWC (Health Assessment Workspace Collaborative): A Modular Web-based Interface to Facilitate Development of Human Health Assessments of Chemicals (<https://hawcproject.org/portal/>).

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

and specify factors that can distinguish among ratings (e.g., what separates “definitely low” from “probably low” risk of bias).

Key Risk-of-bias Questions

In the OHAT approach, some risk-of-bias questions or elements are considered potentially more important when assessing studies because there is more empirical evidence that these areas of bias have a greater impact on estimates of the effect size or because these issues are generally considered to have a greater effect on the credibility of study results in environmental health studies (Rooney *et al.* 2016). There were three Key Questions for observational human studies: confounding, exposure characterization, and outcome assessment. There were also three Key Questions for experimental animal studies: randomization, exposure characterization, and outcome assessment. In addition, for animal developmental studies, failure to consider the litter as the unit of analysis was also a key risk-of-bias concern. When there was not enough information to assess the potential bias for a risk-of-bias question and authors did not respond to an inquiry for further information, a conservative approach was followed, and the studies were rated probably high risk of bias for that question.

Table 4. OHAT Risk-of-bias Questions and Applicability by Study Design						
Risk-of-bias Questions	Experimental Animal*	Human Controlled Trials**	Cohort	Case-Control	Cross-Sectional***	Case Series
1. Was administered dose or exposure level adequately randomized?	X	X				
2. Was allocation to study groups adequately concealed?	X	X				
3. Did selection of study participants result in the appropriate comparison groups?			X	X	X	
4. Did study design or analysis account for important confounding and modifying variables?			X	X	X	X
5. Were experimental conditions identical across study groups?	X					
6. Were research personnel blinded to the study group during the study?	X	X				
7. Were outcome data complete without attrition or exclusion from analysis?	X	X	X	X	X	
8. Can we be confident in the exposure characterization?	X	X	X	X	X	X
9. Can we be confident in the outcome assessment (including blinding of outcome assessors)?	X	X	X	X	X	X
10. Were all measured outcomes reported?	X	X	X	X	X	X
11. Were there no other potential threats to internal validity?	X	X	X	X	X	X

*Experimental animal studies are controlled exposure studies. Non-human animal observational studies can be evaluated using the design features of observational human studies such as cross-sectional study design.

**Human Controlled Trials are studies in humans with controlled exposure (e.g., Randomized Controlled Trials, non-randomized experimental studies)

***Cross-sectional studies include population surveys with individual data (e.g., NHANES) and surveys with aggregate data (i.e., ecological studies).

Any discrepancies in ratings between assessors were resolved by a senior technical specialist and through discussion when necessary to reach the final recorded risk-of-bias rating for each question along with a statement of the basis for that rating. Members of the evaluation team were consulted for assistance if additional expertise was necessary to reach final risk-of-bias ratings based on specific aspects of study design or performance reported for individual studies. Study procedures that were not reported were assumed not to have been conducted, resulting in an assessment of “probably high” risk of bias. Authors were queried by email to obtain missing information and responses received were used to update risk-of-bias ratings.

Table 5. The Four Risk-of-bias Rating Options	
Answers to the risk-of-bias questions result in one of the following four risk-of-bias ratings	
	Definitely Low risk of bias: There is direct evidence of low risk-of-bias practices
	Probably Low risk of bias: There is indirect evidence of low risk-of-bias practices OR it is deemed that deviations from low risk-of-bias practices for these criteria during the study would not appreciably bias results, including consideration of direction and magnitude of bias
 	Probably High risk of bias: There is indirect evidence of high risk-of-bias practices (indicated with “-”) OR there is insufficient information provided about relevant risk-of-bias practices (indicated with “NR” for not reported). Both symbols indicate probably high risk of bias.
	Definitely High risk of bias: There is direct evidence of high risk-of-bias practices

Organizing and Rating Confidence in Bodies of Evidence

Health Outcome Categories for Neurodevelopmental and Cognitive Effects

After data were extracted from all studies, the health effects results within the category of neurodevelopmental or cognitive effects were grouped across studies to develop bodies of evidence or collections of studies with data on the same or related outcomes. The grouping of health effect results was not planned a priori. The vast majority of the human studies evaluated intelligence quotient (IQ) in children as the single outcome; therefore, the discussion of cognitive neurodevelopmental effects in children focuses on IQ studies with supporting information from data on other endpoints. Cognitive function in adults was evaluated separately. Consistent with the NTP (2016) assessment, the primary focus within the animal study body of evidence was on animal studies with endpoints related to learning and memory.

Considerations for Pursuing a Narrative or Quantitative Evidence Synthesis

Heterogeneity within the available evidence was used to determine which type of evidence integration was appropriate—a quantitative synthesis (meta-analysis) or narrative approach for evidence integration. Choi *et al.* (2012) and Duan *et al.* (2018) conducted meta-analyses and found that high fluoride exposure was associated with lower IQ scores. Choi *et al.* (2012) was able to determine a risk ratio for living in an endemic fluorosis area but was unable to develop a dose-response relationship. Duan *et al.* (2018) suggested a significant non-linear dose-response relationship between fluoride dose and intelligence with the relationship stated to be most evident with exposures from drinking water

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

containing above 4 mg/L (or 4 ppm). Duan *et al.* (2018) found similar results as Choi *et al.* (2012) for the standardized mean difference; however, the majority of the available studies in both analyses compare populations with high fluoride exposure to those with lower fluoride exposure (with the lower exposure levels frequently in the range of drinking water fluoridation in the United States). After evaluating the available data, NTP determined that a narrative review—not a meta-analysis or other quantitative assessment—was appropriate for evidence integration due to heterogeneity in dose among the available human evidence, and because a hazard conclusion could be reached without conducting a meta-analysis. However, in the November 2019 review of the September 6, 2019 draft monograph (NASEM 2020), NASEM recommended that a meta-analysis be conducted. In response, NTP performed a meta-analysis of IQ studies in children. The meta-analysis protocol can be found with the revised systematic review protocol posted in September 2020 (<https://ntp.niehs.nih.gov/go/785076>).

Confidence Rating: Assessment of Body of Evidence

The quality of evidence for neurodevelopmental and cognitive function outcomes was evaluated using the GRADE system for rating the confidence in the body of evidence (Guyatt *et al.* 2011, Rooney *et al.* 2014). More detailed guidance on reaching confidence ratings in the body of evidence as “high,” “moderate,” “low,” or “very low” is provided in the OHAT Handbook for Conducting a Literature-Based Health Assessment (<http://ntp.niehs.nih.gov/go/38673>, see STEP 5). In brief, available human and animal studies on a particular health outcome were initially grouped by key study design features, and each grouping of studies was given an initial confidence rating by those features. Starting at this initial rating (see column 1 of [Figure 1](#)), potential downgrading of the confidence rating was considered for factors that decrease confidence in the results (see column 2 of [Figure 1](#) [risk of bias, unexplained inconsistency, indirectness or lack of applicability, imprecision, and publication bias]); and potential upgrading of the confidence rating was considered for factors that increase confidence in the results (see column 3 of [Figure 1](#) [large magnitude of effect, dose response, consistency across study designs/populations/animal models or species, consideration of residual confounding, and other factors that increase our confidence in the association or effect]). Consideration of consistency across study designs, human populations, or animal species is not included in the GRADE guidance (Guyatt *et al.* 2011); however, it is considered in the modified version of GRADE used by OHAT (Rooney *et al.* 2014, NTP 2015).

Figure 1. Assessing Confidence in the Body of Evidence

Confidence ratings were assessed by the evaluation team for accuracy and consistency, and discrepancies were resolved by consensus and consultation with technical advisors as needed. Confidence ratings for the primary outcomes are summarized in evidence profile tables for each outcome.

Preparation of Level of Evidence Conclusions

The confidence ratings were translated into level of evidence of health effects for each type of health outcome separately according to one of four statements: (1) High, (2) Moderate, (3) Low, or (4) Inadequate (see [Figure 2](#)). The descriptor “evidence of no health effect” is used to indicate confidence that the substance is not associated with a health effect. Because of the inherent difficulty in proving a negative, the conclusion “evidence of no health effect” is only reached when there is high confidence in the body of evidence.

Figure 2. Translate Confidence Ratings into Evidence of Health Effect Conclusions

Integrate Evidence to Develop Hazard Identification Conclusions

Finally, the levels of evidence ratings for human and animal data were integrated with consideration of in vitro/mechanistic data to reach **one of five possible hazard identification categories: (1) Known, (2) Presumed, (3) Suspected, (4) Not classifiable, or (5) Not identified to be a neurodevelopmental hazard to humans (see Figure 3).**

Consideration of Human and Animal Data

Initial hazard identification conclusions were attempted by integrating the highest level-of-evidence conclusion for neurodevelopmental effects in children and cognitive effects in adults for the human and the animal evidence streams. The level-of-evidence conclusion for human data for neurodevelopmental or cognitive effects were considered with the level of evidence for non-human animal data to reach one of four initial hazard identification conclusions: Known, Presumed, Suspected, or Not classifiable. When either the human or animal evidence stream was characterized as “Inadequate Evidence,” then conclusions were based on the remaining evidence stream alone (which is equivalent to treating the missing evidence stream as “Low” in Figure 3). If a moderate level-of-evidence conclusion for human data was reached with “Inadequate or Low Evidence” for the animal evidence stream, a hazard identification conclusion of either “suspected to be a hazard to humans” or “presumed to be a hazard to humans” could be reached based on scientific judgement as to the robustness of the body of evidence that supports moderate confidence in the human data and consideration of the potential impact of additional studies (NTP 2019).

Consideration of Mechanistic Data

There is no requirement to consider mechanistic or mode-of-action data to reach a hazard identification conclusion regarding neurodevelopmental or cognitive health effects. However, when available, this and other relevant supporting types of evidence may be used to raise (or lower) the category of the hazard identification conclusion. Mechanistic data can come from a wide variety of studies that are not intended to identify a disease phenotype. This source of experimental data includes in vitro and in vivo laboratory studies directed at cellular, biochemical, genetic, and molecular mechanisms that attempt to explain how a chemical produces particular adverse effects.

For the evaluation of toxicity associated with fluoride exposure, NTP was interested in mechanistic or in vitro measures that comprise a coherent biological process that may support the plausibility of corresponding neurological outcomes reported from in vivo studies in animals or humans. The PECO statement in [Table 3](#) provides the specific endpoints considered including neuronal electrophysiology; mRNA, gene, or protein expression; cell proliferation or death in brain or thyroid tissue/cells; neuronal signaling; or synaptogenesis. In general, the mechanisms for fluoride-associated neurodevelopmental or cognitive effects are not well understood at this time, and mechanistic events identified in studies of animals receiving high fluoride exposures may not reflect biological processes occurring in humans at lower exposure levels. Mechanistic data from in vivo studies were used when feasible to examine the biological plausibility of the primary health outcomes considered in developing a hazard conclusion.

The factors outlined for increasing or decreasing confidence that the mechanistic data support biological plausibility are conceptually similar to those used to rate confidence in bodies of evidence for human or

animal in vivo studies are listed below and described in depth in the protocol (<https://ntp.niehs.nih.gov/go/785076>). Four factors were considered that contribute to increased confidence: potency, dose response, consistency in terms of cellular events observed at the same or lower doses than in vivo health effects, and consistency across cellular targets on the same functional pathway. Three factors were considered that contribute to decreased confidence: unexplained inconsistency across studies of the same endpoint, indirectness/applicability of the pathway for human health or concentrations for human exposure, and publication bias. Evaluations of the strength of evidence provided by mechanistic data were made on an outcome-specific basis based on discussion by the evaluation team and consultation with technical advisors as needed.

- If mechanistic data provided strong support for biological plausibility of the relationship between exposure and the health effect, the hazard identification conclusion may be upgraded (indicated by black “up” arrows in **Figure 3**) from that initially derived by considering the human and non-human animal evidence together.
- If mechanistic data provided strong opposition for biological plausibility of the relationship between exposure and the health effect, the hazard identification conclusion may be downgraded (indicated by gray “down” arrows in **Figure 3**) from that initially derived by considering the human and non-human animal evidence together.

Although it is envisioned that strong evidence for a relevant neurological effect from mechanistic data alone could indicate a potential that the substance is a neurodevelopmental hazard to humans, for this evaluation the mechanistic data were only considered to inform the biological plausibility of observed outcomes from in vivo exposure studies in humans or animals because of a general lack of understanding of the mechanistic basis for neurological outcomes.

RESULTS AND EVIDENCE SYNTHESIS

Literature Search Results

Literature Search Results Counts and Title and Abstract Screening

The electronic database searches retrieved 25,524 unique references in total (20,883 references during the initial search conducted in December 2016, 3,733 references during the literature search updates [including the final updated search conducted for the primary epidemiology studies on May 1, 2020], and 908 references from the supplemental Chinese database searches); 15 additional references were identified by technical advisors or from reviewing reference lists in published reviews and included studies. As a result of title and abstract screening, 1,038 references were moved to full-text review, 11,478 were excluded during manual title and abstract screening for not satisfying the PECO criteria, and an additional 13,023 were not screened and excluded based on the SWIFT algorithm.

Full-text Review

Among the 1,038 references that underwent full-text review, 499 references were excluded during the full-text review with reasons for exclusion documented at this stage; 332 references were excluded for not satisfying the PECO criteria; and 167 references from the May 2020 searches (main literature search update and supplemental Chinese database searches) were excluded for not including information that would materially advance the human, animal in vivo, or mechanistic findings (see the Literature Search Section for a description of the methodology). These screening results are outlined in a study selection diagram that reports numbers of studies excluded for each reason at the full text review stage (see [Figure 4](#)) [using reporting practices outlined in Moher *et al.* (2009)]. After full-text review, 539 studies were considered relevant with primary neurological outcomes, secondary neurological outcomes, and/or outcomes related to thyroid function (see [Appendix 2](#)). A few studies assessed data for more than one evidence stream (human, non-human mammal, and/or in vitro), and several human and animal studies assessed more than one type of outcome (e.g., primary and secondary outcomes). The number of included studies is summarized below. There are:

- 159 human studies (78 primary only; 13 secondary only; 5 primary and secondary; 6 primary and thyroid; 2 secondary and thyroid; and 55 thyroid only);
- 339 non-human mammal studies (7 primary only; 186 secondary only; 67 primary and secondary; 6 primary, secondary, and thyroid; 4 secondary and thyroid; and 69 thyroid only); and,
- 60 in vitro/mechanistic studies (48 neurological and 12 thyroid).

One publication contained human, experimental non-human mammal, and in vitro data. Three publications contained both human and experimental non-human mammal data. Fourteen publications contained data relevant to both experimental non-human mammal studies and in vitro studies.

Evaluation of SWIFT-Active Screener Results

During the initial title and abstract screening of 20,883 references using SWIFT-Active Screener, approximately 38%⁶ of the 20,883 studies were manually screened in duplicate to identify an estimated 98.6% of the predicted number of relevant studies using the statistical algorithm in SWIFT-Active Screener (13,023 references were not screened). SWIFT-Active Screener predicted that there were 739 relevant studies during the initial title and abstract screening, of which 729 studies were identified and moved to full-text review. The SWIFT-Active statistical algorithm predicted that 10 relevant studies at the title and abstract level (10 represents $1.4\% \times 739$ predicted relevant studies; or 739 predicted relevant studies minus 729 identified relevant studies during screening) were not identified by not screening the remaining 13,023 studies.

To further consider the impact of using SWIFT-Active Screener for this systematic review, NTP evaluated the SWIFT-Active screening results to gain a better understanding of the relevance of the last group of studies that were screened before 98% predicted recall was satisfied. The goal was to determine the likelihood of having missed important studies by not screening all of the literature. To do this, NTP evaluated subsets of studies screened in SWIFT-Active for trends and followed those studies through to full-text review for a final determination of relevance and potential impact (i.e., whether the studies had data on primary outcomes). Based on this evaluation, NTP estimates that the use of Swift-Active Screener may have resulted in missing 1–2 relevant human studies and 1–2 relevant animal studies with primary neurodevelopmental or cognitive outcomes.

Supplemental Chinese Database Searches and Human Epidemiology Studies

Following the NASEM committee peer review in November 2019 (NASEM 2020), supplemental searches were conducted in non-English language databases (CNKI and Wanfang). One focus of the screening of these supplemental search results was to identify null or no-effect studies that evaluated primary neurodevelopmental or cognitive outcomes (learning, memory, and intelligence) that may have been missed in previous approaches or may have been absent from the Fluoride Action Network website. Of the 908 references that were identified in the supplemental Chinese database searches, 16 relevant studies with primary neurological outcomes were identified (which were not identified through the main literature searches). Among these 16 studies, Kang *et al.* (2011) was the only null study with primary neurological outcomes that was identified through the supplemental Chinese database searches. NTP had the study translated to English, and the study was included. Note that Kang *et al.* (2011) is also identified by the Fluoride Action Network as a null study, but their website does not include an English translation of the study. The other 15 relevant studies contained results that would likely add to the body of evidence showing a negative association between fluoride exposure and primary neurological outcomes. Because this body of evidence is already so large, and because time was a factor in the revision of the monograph, these studies were not translated or included as this information would likely not materially advance the human findings.

⁶ Howard *et al.* (2020) evaluated the performance of the SWIFT-Active Screener methods for estimating total number of relevant studies using 26 diverse systematic review datasets that were previously screened manually by reviewers. The authors found that on average, 95% of the relevant articles were identified after screening 40% of the total reference list when using SWIFT-Active Screener. In the document sets with 5,000 or more references, 95% of the relevant articles were identified after screening 34% of the available references, on average, using SWIFT-Active Screener.

Figure 4. Study Selection Diagram

* Studies may have been excluded for more than one reason; the first reason identified by the screener was recorded.

** Animal in vivo, human secondary outcome-only, and human and animal mechanistic references from the 2020 database searches were scanned for evidence that might strengthen the information in the September 6, 2019 draft monograph. Although 145 additional animal in vivo and/or mechanistic studies and 7 additional human secondary outcome-only or mechanistic-only studies were identified, information that would materially advance the human, animal in vivo, and mechanistic findings was not identified; therefore, these studies were not included. Additionally, 15 human primary outcome studies from the 2020 Chinese database search were excluded based on English abstracts and google translations because information that would materially advance the human findings was not identified; 1 null publication from the 2020 Chinese database search (Kang *et al.* 2011) was identified, translated, and included.

*** One publication contained human, experimental non-human mammal, and in vitro data. Three publications contained both human and experimental non-human mammal data. Fourteen publications contained data relevant to both experimental non-human mammal studies and in vitro studies.

Neurodevelopmental and Cognitive Health Effects Results

All the neurodevelopmental and cognitive data were initially considered and evaluated, with more in-depth analysis where similar endpoints were evaluated across multiple studies (e.g., IQ). Hazard conclusions were developed separately for two different age groups (i.e., children and adults) to address potential differences in the health impact based on exposure during development compared to adulthood. Although the data cover a wide array of endpoints (see Figure 5), the hazard conclusion covers a single category for each age group. The largest bodies of evidence were for IQ (n = 71 studies), learning and memory (n = 8 studies), as well as other cognitive development effects (e.g., total

neurobehavioral scores and total mental capacity index in children and cognitive impairment in adults; n = 14 studies)⁷. Due to heterogeneity in the endpoints examined and the limited number of human or animal studies, congenital neurological malformations and neurological complications of fluorosis were not evaluated because the body of evidence was inadequate to evaluate these potential effects. These health outcomes are not further discussed in this assessment. To the extent possible, human and animal data were grouped into similar categories (e.g., IQ in humans was considered comparable to learning and memory in animals). NTP had previously assessed animal data related to effects on learning and memory associated with fluoride exposure (NTP 2016). Therefore, to update the conclusions of the NTP (2016) systematic review, only more recent animal studies were evaluated in this assessment. Although the previous NTP (2016) report was conducted through January 14, 2016, the current assessment included studies published from 2015 through April 2019 and considered studies from the NTP (2016) report. Thirty-five animal studies have been identified that met these criteria, including 23 studies with learning and memory endpoints and 12 studies with only motor and sensory endpoints. Consistent with the NTP (2016) assessment, only learning and memory studies have been considered in the development of hazard identification conclusions. The additional motor and sensory studies have been considered, along with information on motor and sensory effects reported in the learning and memory studies, to provide evidence of possible indirectness related to the learning and memory assessments.

Risk-of-bias Considerations

Risk-of-bias ratings for each individual study for all risk-of-bias questions are available in [Appendix 3](#). The risk of bias of individual studies in the body of evidence was considered in developing confidence ratings. The key risk-of-bias questions (i.e., confounding, exposure characterization, and outcome assessment for human studies and randomization, exposure characterization, and outcome assessment for experimental animal studies) are discussed in the consideration of the body of evidence. For this assessment, the key risk-of-bias questions, if not addressed appropriately, are considered to potentially have the greatest impact on the results. In addition, for developmental studies in animals, controlling for potential litter effects (i.e., adjusting for similarities in responses between littermates) was also a key risk-of-bias concern. The other risk-of-bias questions were also taken into consideration and were used to identify any other risk-of-bias concerns that may indicate serious issues with the studies. No study was excluded based on concerns for risk of bias; however, confidence conclusions were considered with and without higher risk-of-bias studies (i.e., studies rated probably high risk of bias for at least two key risk-of-bias questions or definitely high for any single question) to assess the impact of the higher risk-of-bias studies. The remaining studies (i.e., other than the higher risk-of-bias studies) were considered lower risk of bias. Based on NASEM recommendations (NASEM 2020), [Appendix 4](#) was created for the lower risk-of-bias studies to describe strengths and limitations of the studies identified during the assessment and to clarify why they are considered to pose lower risk of bias.

Human Neurodevelopmental and Cognitive Data

While there were several neurodevelopmental and cognitive endpoints assessed (see [Figure 5](#)), most of the available studies evaluated intelligence (e.g., IQ) in children. Other measures of neurodevelopment or cognitive function in children were also assessed, including general cognitive index (GCI), mental capacity, mental development index (MDI), or neonatal behavioral neurological assessment (NBNA). However, because the majority of studies evaluated intelligence, the discussion focuses primarily on IQ in children with separate discussions on other measures of cognitive function and neurobehavioral

⁷Some studies are included in more than endpoint category (e.g., IQ and other cognitive developmental effects); therefore, these counts are not mutually exclusive.

effects in children and cognitive effects in adults. The available body of literature that evaluates the association between fluoride exposure and neurodevelopmental and cognitive effects is relatively robust ($n = 92$) and confidence considerations in the body of evidence and hazard conclusions are focused on the studies with the least potential for bias ($n = 31$). Studies with higher potential for bias ($n = 61$) have also been evaluated and determined to have little impact on the confidence and hazard conclusions. A subgroup analysis within the meta-analysis (described in detail in [Appendix 5](#)) demonstrated that results were robust to the exclusion of higher risk-of-bias studies (see [Appendix 5, Figure A5-6](#)). All evaluated studies can be found in [Appendix 2](#).

This section is organized to present and explain NTP's two confidence ratings in the bodies of evidence from epidemiological studies that fluoride exposure is associated with cognitive neurodevelopmental effects in children and cognitive effects in adults. These confidence ratings were determined as described in [Figure 1](#).

Summary: There is moderate confidence in the body of evidence that fluoride exposure is associated with cognitive neurodevelopmental effects in children, and low confidence in the body of evidence that fluoride exposure is associated with cognitive effects in adults. The moderate confidence rating is supported by consistent evidence from the available studies of an association between high-fluoride exposure (mainly greater than the WHO Drinking Water Quality Guideline [>1.5 mg/L] (WHO 2011), but also high exposure via fluoridated salt and food) and lower IQ or cognitive function in children. There is also a recent study of lower IQ in children living in areas where drinking water fluoride concentrations are <1.5 mg/L. Specifically, a study conducted in Canada observed significantly lower IQ scores in boys and girls associated with higher estimated total maternal consumption of fluoride during pregnancy from drinking water and other water-based beverages including black and green tea. When looking at maternal urinary fluoride concentrations, the significant negative association with IQ scores was seen in boys but not girls (Green *et al.* 2019). Another study conducted in Mexico with similar maternal urinary fluoride concentrations during pregnancy as seen in Green *et al.* (2019) observed significantly lower IQ scores in boys and girls associated with higher perinatal exposure to fluoride (Bashash *et al.* 2017). Although the body of evidence in children supports lower IQ with increased fluoride exposure, there is a lack of evidence of an association between exposure to fluoride and cognitive effects in adults (Jacqmin *et al.* 1994, Li *et al.* 2016). The body of evidence available to examine the association between exposure to fluoride and cognitive effects in adults is limited to two lower risk-of-bias cross-sectional studies; due to the limited number of studies and a lack of an observed effect, this body of evidence is considered inadequate to evaluate whether fluoride exposure is associated with cognitive effects in adults (see [Table 7](#)).

Most of the available epidemiological studies that evaluated the association between fluoride exposure and cognitive neurodevelopmental effects assessed IQ and other measures of cognitive function in children (see [Figure 5](#)). Confidence conclusions are based on those studies with the lowest potential for bias ($n = 28$; 26 in children and 2 in adults) (see [Table 6](#)). Most of these studies measured fluoride levels in drinking water or urine. All but two of the studies were conducted in infants or children. The two studies in adults were conducted in older adult populations (≥ 60 years old; one in France and the other in a fluorosis-endemic area of China) to evaluate the effects of fluoride on cognitive impairment.

The studies in children were conducted in multiple populations. Of the 26 studies in children:

- 12 were conducted in 6 areas of China based on 8 study populations (1 study with both IQ and other neurodevelopmental outcomes, 9 studies with IQ only, and 2 studies with other neurodevelopmental outcomes);
- 6 were conducted in 4 areas of Mexico based on 5 study populations (1 study with both IQ and other neurodevelopmental outcomes, 2 studies with IQ only, and 3 studies with other neurodevelopmental outcomes);
- 4 were conducted in Canada using 2 separate cohorts (2 studies with IQ only and 2 studies with other neurodevelopmental outcomes);
- 3 were conducted in 3 areas of India (all IQ studies); and
- 1 was conducted in Iran (IQ study).

The IQ studies used many different tests to measure IQ. The IQ tests used often differed by population as not all IQ tests are appropriate for all populations (e.g., western vs. Asian populations). In some cases, different IQ tests were used to study similar populations. Overall, studies used IQ or cognitive tests appropriate for the population and were age appropriate. Other neurodevelopmental outcomes assessed in some studies included neurobehavioral effects (in infants), learning and memory impairment, and learning disabilities such as attention deficit hyperactivity disorder (ADHD). The different tests conducted and the populations on which the tests were conducted are indicated in [Table 6](#).

The lower risk-of-bias studies (i.e., studies not meeting criteria for higher risk of bias) showing associations with cognitive neurodevelopmental effects in children include 5 prospective cohort studies from 3 study populations (Bashash *et al.* 2017, Valdez Jimenez *et al.* 2017, Green *et al.* 2019, Bashash *et al.* 2018, Till *et al.* 2020) and 21 cross-sectional studies from 16 study populations (Li *et al.* 2004 [translated in Li *et al.* 2008a], Choi *et al.* 2015, Rocha-Amador *et al.* 2007, Rocha-Amador *et al.* 2009, Saxena *et al.* 2012, Seraj *et al.* 2012, Xiang *et al.* 2003a, Xiang *et al.* 2011, Zhang *et al.* 2015b, Ding *et al.* 2011, Barberio *et al.* 2017b, Yu *et al.* 2018, Cui *et al.* 2018, Cui *et al.* 2020, Wang *et al.* 2020b, Wang *et al.* 2020a, Wang *et al.* 2012, Soto-Barreras *et al.* 2019, Sudhir *et al.* 2009, Trivedi *et al.* 2012, Riddell *et al.* 2019) (see [Figure D1](#) through [Figure D12](#)). One limitation of the 21 cross-sectional studies was the lack of direct evidence that exposure to fluoride occurred prior to the development of the neurodevelopmental outcomes. However, several studies from different study populations (n = 5) indicated that a large portion of the exposed children had dental fluorosis (ranging from 43–100%) at the time of the assessment (Choi *et al.* 2015, Ding *et al.* 2011, Seraj *et al.* 2012, Yu *et al.* 2018, Sudhir *et al.* 2009). Because dental fluorosis occurs when fluoride is consumed during enamel formation usually during the first 6–8 years of life, the presence of dental fluorosis suggests that exposures to fluoride occurred prior to the outcome assessment. Ten studies from seven study populations (including Yu *et al.* (2018), Wang *et al.* (2012) listed above) excluded subjects that had not lived in the study area for a specified period of time, sometimes since birth (Rocha-Amador *et al.* 2007, Rocha-Amador *et al.* 2009, Saxena *et al.* 2012, Yu *et al.* 2018, Wang *et al.* 2020b, Wang *et al.* 2012, Xiang *et al.* 2011, Xiang *et al.* 2003a, Soto-Barreras *et al.* 2019, Sudhir *et al.* 2009). Another study evaluated fluoride exposure in mothers and included urine levels just prior to birth and assessed children a few days after birth (Li *et al.* 2004 [translated in Li *et al.* 2008a]). Because these areas were generally known to be fluoride-endemic areas for long periods of time, it can generally be assumed that in these 14 cross-sectional studies from 11 study populations, exposure occurred prior to the outcome. These exposure concerns were not an issue for the prospective studies because fluoride levels were measured prenatally. Therefore, the moderate confidence in the body of evidence in children is primarily based on the consistency of findings across different populations in the 5 lower risk-of-bias prospective cohort studies and the 14

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

cross-sectional studies where exposure is considered to have occurred prior to the outcome with initial and final ratings of moderate confidence.

Adult Studies					
Jacqmin <i>et al.</i> (1994)	Cross-sectional France (Gironde and Dordogne)/elderly adults [3,490]	Drinking water Range: 0.03–2.03 mg	Adults (ages ≥ 65 years)	Cognitive function: Mini-Mental State (MMS) Examination	No significant increase in the prevalence of cognitive impairment with increasing fluoride quartiles No statistical adjustment for confounders
Li <i>et al.</i> (2016)	Cross-sectional China (Inner Mongolia)/adults [511]	Drinking water intake and urinary fluoride Mean (SD) levels reported for a subset of subjects with normal scores (2.23 [2.23] mg and 1.46 [1.04] mg/L, respectively) and subjects with cognitive impairment (3.62 [6.71] mg and 2.47 [2.88] mg/L, respectively)	Adults (ages ≥ 60 years)	Cognitive function: MMS Examination	Results suggested that degree of fluoride exposure was consistent with severity of skeletal fluorosis, and fluoride exposure may be a risk factor for cognitive impairment; however, neither water fluoride intake (adjusted ORs = 0.94 [95% CI: 0.85, 1.04] and 0.86 [95% CI: 0.69, 1.06] in the moderate and severe cognitive impairment groups, respectively) nor urinary fluoride levels (adjusted ORs = 1.12 [95% CI: 0.89, 1.42] and 1.25 [95% CI: 0.87, 1.81] in the moderate and severe cognitive impairment groups, respectively) were significantly correlated with cognitive impairment Adjusted for sex, age, education, marital status (married vs. not married), alcohol consumption (non-drinkers, light drinkers, moderate to heavy drinkers), smoking history (never smoker, ex-smoker, light smoker, heavy smoker), and serum homocysteine levels

*Three additional publications based on subsample (i.e., 50–60 children) of the larger Yu *et al.* (2018) cohort were identified (Zhao *et al.* 2020, Zhou *et al.* 2019, Zhao *et al.* 2019); however, these publications focused on mechanistic considerations and are not included in the study totals for IQ because the main study by Yu *et al.* (2018) is considered a better representation of the IQ results.

^aIncludes lower risk-of-bias studies.

^bDefinitions: **ADHD**: attention-deficit/hyperactivity disorder; **GCI**: General Cognitive Index; **GM**: geometric mean; **HOME**: Home Observation Measurement of the Environment; **IQ**: intelligence quotient; **MSCA**: McCarthy Scales of Children’s Abilities; **WASI**: Wechsler Abbreviated Scale of Intelligence (Spanish version); **WISC-IV**: Wechsler Intelligence Scale for Children-Revised; **WRAML**: Wide Range Assessment of Memory and Learning; **WRAVMA**: Wide Range Assessment of Visual Motor Ability.

Overall Risk-of-bias Discussion of the Body of Evidence

The confidence rating for the body of evidence in humans was based on studies with the lowest potential for bias (i.e., studies rated probably low or definitely low risk of bias for at least two of the three key risk-of-bias questions). Each of these 28 studies (including 26 studies in children and 2 in adults) had little or no risk-of-bias concerns, and confidence in the body of evidence was not

downgraded for risk of bias. However, the remaining studies in the human body of evidence were rated as probably high or definitely high risk of bias for at least two key risk-of-bias questions or had other major concerns. Risk-of-bias ratings for individual studies for all questions are available in [Figure A3-1](#) and [Figure A3-3](#). Among the studies with lower potential for bias (see [Figure A3-1](#) and [Figure A3-2](#)), the key risk-of-bias question with the most potential for bias was the potential for confounding. Potential confounding was a concern for 5 of the 26 lower risk-of-bias studies in children (see *Confounding* for further discussion). Among the studies with higher overall potential for bias, there were a number of risk-of-bias concerns, including potential confounding, poor exposure characterization, poor outcome assessment, and, in many cases, potential concern with participant selection (see [Figure A3-3](#) and [Figure A3-4](#)). Many of the studies (n = 32) included in the entire human body of evidence were initially published in a foreign language (mainly Chinese) and were either translated and published in volume 41 of the journal *Fluoride* (n = 19) or were translated by the Fluoride Action Network (n = 13) (http://fluoridealert.org/researchers/translations/complete_archive/). Most of these studies were considered to have high potential for bias due to lack of information across many key risk-of-bias questions. Therefore, in order to assess if the lack of information relevant to key risk-of-bias concerns was the result of a loss in translation, the original Chinese publications and the translated versions of the five studies that had the most potential for being included in the lower risk-of-bias group of studies were reviewed to determine if any of the risk-of-bias concerns could be addressed (An *et al.* 1992, Chen *et al.* 1991 [translated in Chen *et al.* 2008], Du *et al.* 1992 [translated in Du *et al.* 2008], Guo *et al.* 1991 [translated in Guo *et al.* 2008a], Li *et al.* 2009). For all five studies, the translations were determined to be accurate and there was no impact on the key risk-of-bias concerns.

Confounding

Potential confounding variables and/or effect modifiers that were considered key for all studies, populations, and outcomes included child's age, child's sex, and socioeconomic status (e.g., maternal education, household income, marital status, crowding). Additional potential confounding variables and/or effect modifiers considered important for this evaluation depending on the study population and outcome included race/ethnicity; maternal demographics (e.g., maternal age, body mass index [BMI]); parental behavioral and mental health disorders (e.g., ADHD, depression); smoking (e.g., maternal smoking status, secondhand tobacco smoke exposure); reproductive factors (e.g., parity); nutrition (e.g., BMI, growth, anemia); iodine deficiency/excess; minerals and other chemicals in water associated with neurotoxicity (e.g., arsenic, lead); maternal and paternal IQ; and quantity and quality of caregiving environment (e.g., Home Observation Measurement of the Environment [HOME] score). To be assigned a rating of probably low risk of bias for the key risk-of-bias question regarding confounding, studies were not required to address every potential confounder listed; however, studies were required to address the three key covariates for all studies, the potential for co-exposures if applicable (e.g., arsenic and lead, both of which could affect cognitive function), and any other potential confounders considered important for the specific study population and outcome. For example, studies of populations in China, India, and Mexico, where there is concern for exposures to high fluoride and high arsenic, were required to address arsenic, and smoking needed to be addressed in studies of adults when dementia was evaluated. In order to identify areas of China, India, and Mexico where arsenic is a concern, groundwater quality maps were evaluated (<https://www.gapmaps.org/Home/Public#>) (Podgorski and Berg 2020). If no arsenic measurements were available for the area, the arsenic groundwater quality predictions from the global arsenic 2020 map were used (Podgorski and Berg 2020). If an area had less than 50% probability of having arsenic levels greater than 10 µg/L (the WHO guideline concentration), the area was considered not to have an issue with arsenic that needed to be addressed by the study authors.

Among studies with lower risk-of-bias concerns, 21 of the 26 studies were considered to have lower potential for bias due to confounding. Relative to confounders considered key for all studies and populations (i.e., age, sex, and SES), one study did not address age, one study did not address sex, and two studies did not account for indicators of SES (e.g., parental education, household income). Nine of the 26 lower risk-of-bias studies accounted for maternal or family member smoking. Potential confounding related to co-exposure to arsenic was not accounted for in five lower risk-of-bias studies and was the main potential concern in these studies; however, three of these studies (Xiang *et al.* 2011, Wang *et al.* 2012, Xiang *et al.* 2003a) were still considered low risk of bias for confounding due to the fact that arsenic was observed in the low fluoride areas (which would bias the effect toward the null), but an effect was still observed. The other two studies did not address arsenic and were in areas that had potential for arsenic exposure to occur (Soto-Barreras *et al.* 2019, Valdez Jimenez *et al.* 2017). Seven studies did not consider co-exposures to lead; however, for all of these studies this co-exposure was considered unlikely to have an impact in these study populations as there was no evidence that lead was prevalent or occurring in relation to fluoride.

Although there is variability in the potential confounders considered and differences in populations evaluated, the consistency of the results among the lower risk-of-bias studies indicates that confounding is not a major concern in this body of evidence. Even though 5 of 26 lower risk-of-bias studies in children are considered to have higher potential for bias due to confounding that could not be ruled out for that specific population and outcome (see [Figure 6](#)), results were consistent across multiple populations; all but two of the lower risk-of-bias studies in children reported an association between higher fluoride exposure and lower IQ or another cognitive effect. Seven of the lower risk-of-bias studies confirmed the robustness of the results by conducting sensitivity analyses (Bashash *et al.* 2018, Bashash *et al.* 2017, Green *et al.* 2019, Yu *et al.* 2018, Wang *et al.* 2020a, Wang *et al.* 2020b, Till *et al.* 2020). None of the sensitivity analyses adjusting for additional confounders found meaningful shifts in the association between fluoride exposure and IQ or other measures of cognitive function. Bashash *et al.* (2017) found that adjusting for HOME score increased the association between maternal urinary fluoride and children's IQ. Bashash *et al.* (2018) examined several potential confounders in sensitivity analyses involving subsets of participants, including HOME scores, child contemporaneous fluoride exposure measured by child urinary fluoride adjusted for specific gravity, and maternal lead and mercury exposures. The authors reported that no sensitivity analyses indicated appreciable changes in the fluoride-related association with behaviors related to ADHD, nor did they find evidence of effect modification between sex and maternal urinary fluoride. Green *et al.* (2019) found that adjusting for lead, mercury, manganese, perfluorooctanoic acid, and arsenic concentrations did not substantially alter the associations with IQ. Sensitivity analyses by Yu *et al.* (2018) that adjusted for covariates (including age, sex, and socioeconomic status) did not find differences in the results compared to the primary analyses. Both Wang *et al.* (2020a) and Wang *et al.* (2020b) found the results of the sensitivity analysis to be the same as the results from the preliminary analysis. Till *et al.* (2020) found that adjusting for maternal urinary fluoride levels had little effect on the results.

As previously mentioned, most of the higher risk-of-bias studies in the human body of evidence did not address the potential confounders of greatest concern. Many of these studies conducted only simple statistical analyses without accounting for any potential confounders (50 of 61 higher risk-of-bias studies), and many studies did not report whether the study subjects were from areas of similar socioeconomic status or environmental conditions (n = 20 higher risk-of-bias studies). Potential confounding related to important co-exposures (e.g., arsenic and lead) was often not addressed in higher risk-of-bias studies. In studies where there was high exposure to fluoride via drinking water with high naturally-occurring fluoride or from the use of coal-containing fluoride, most researchers did not

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

account for potential exposures to arsenic, which is commonly found in coal and drinking water in fluoride-endemic areas of China and Mexico. In general, researchers did not account for potential exposures to lead; however, studies reporting lead levels in fluoride-endemic areas, including areas in China, often reported low levels of lead (Xiang *et al.* 2011, Choi *et al.* 2012, Seraj *et al.* 2012, Choi *et al.* 2015, Yu *et al.* 2018, Saxena *et al.* 2012, Xiang *et al.* 2003b). Therefore, lead is not assumed to be a common exposure in fluoride-endemic areas. Most of the studies did not account for smoking or socioeconomic status, nor did they provide information to lessen the risk-of-bias concern (e.g., list of study characteristics indicating no significant differences between comparison groups). However, as noted for the lower risk-of-bias studies, given the consistency of the evidence, confounding among higher risk-of-bias studies is likely less of a concern for the body of evidence as a whole than for any individual study.

Notes:

¹Includes all lower risk-of-bias studies in children. Studies are organized as those with an overall risk-of-bias rating for confounding as probably low (green) followed by those with an overall risk-of-bias rating for confounding as probably high (yellow).

²Potential confounding factors and/or effect modifiers represented here are those considered important for this evaluation. See study details provided in HAWC for information on additional confounders.

Factors outlined in blue (subject age, subject sex, arsenic, SES) are considered key confounders.

A √ indicates that a factor was considered (and may or may not have been adjusted for in final model). For 'Other Exposures', a √ might also be used when a co-exposure was not expected to be an issue because there is no evidence to indicate that the co-exposure was prevalent or occurring in relation to fluoride. See risk-of-bias explanations in HAWC for details. A hyphen (-) indicates that the factor was not considered.

³See the "Notes" column for additional details.

⁴Extent of reported effects varies by study. "Yes" indicates that study authors reported one or more significant effects on IQ or other cognitive functions associated with fluoride exposure.

Exposure assessment

Exposure was assessed using a variety of methods in the human body of evidence. Studies provided varying levels of details on the methods used and employed different exposure characterization methods to group study subjects into exposed and reference groups. Exposure metrics included spot urine (from children or mothers during at least one trimester), serum, individual drinking water, intake from infant formula, estimated total exposure dose, municipal drinking water (with residence information), area of residence (endemic versus a non-endemic fluorosis area with or without individual validation of exposure), burning coal (with or without fluoride), and occupation type. Analytical methods to measure fluoride in biological or water samples also varied, some of which included atomic absorption, ion selective electrode methods, colorimetric methods, or the hexamethyldisiloxane microdiffusion method. Individual-level measures of exposure were generally considered more accurate than group-level measures; however, using group-level measures (e.g., endemic versus non-endemic area) in an analysis was less of a concern if the study provided water or urine fluoride levels from some individuals to verify that there were differences in the fluoride exposure between groups. Studies that provided results by area but also reported individual urinary or serum fluoride concentrations or other biochemical measures, including dental fluorosis in the children or urinary levels in mothers during pregnancy, were considered to have probably low risk of bias.

In general, there were few or no risk-of-bias concerns regarding exposure assessment in the lower risk-of-bias studies. Many of the lower risk-of-bias studies used individual urine or water measures with appropriate analyses. Urinary fluoride levels include all ingested fluoride and are considered a valid measure to estimate fluoride exposure (Villa *et al.* 2010, Watanabe *et al.* 1995); however, some concerns exist. Urinary fluoride is thought to reflect recent exposure but can be influenced by the timing of exposure (e.g., when water was last consumed, when teeth were last brushed). When compared to 24-hour urine samples, spot urine samples are more prone to these influences and can also be affected by differences in dilution; however, many studies attempted to account for dilution either using urinary creatinine or specific gravity. Good correlations between 24-hour samples and urinary fluoride concentrations from spot samples adjusted for urinary dilution have been described (Zohouri *et al.* 2006). Despite potential issues with spot urine samples, if authors made appropriate efforts to reduce the concern for bias, studies that used this metric were generally considered to have probably low risk of bias for exposure.

Although there are concerns related to using maternal urine samples, many studies provide evidence to suggest that urinary fluoride is a reasonable measure of exposure. Using three methods to account for urine dilution, Till *et al.* (2018) reported that adjusted risk estimates did not differ from unadjusted estimates. Analyzing the same study population as Till *et al.* (2018), Green *et al.* (2019) found that adjusting for time of urine collection or time of collection since last void during pregnancy did not substantially affect associations with IQ results in either boys or girls. In addition, adjusting the maternal urinary fluoride for creatinine did not substantially alter the association observed (Green *et al.* 2019). To provide a more accurate and sensitive measurement of maternal urinary fluoride than a single measurement provides, Green *et al.* (2019) only included participants with valid fluoride measurements at each trimester in their analysis. Several other studies also measured urinary fluoride multiple times throughout pregnancy (Bashash *et al.* 2018, Bashash *et al.* 2017, Green *et al.* 2019, Valdez Jimenez *et al.* 2017). Other studies demonstrated correlations between the urinary fluoride and fluoride in the drinking water, fluorosis, or estimated dose based on water (Green *et al.* 2019, Saxena *et al.* 2012, Zhang *et al.* 2015b, Ding *et al.* 2011, Choi *et al.* 2015, Yu *et al.* 2018). Till *et al.* (2018) demonstrated that there was a linear association between urinary fluoride concentrations in pregnant women and drinking water fluoride concentrations regardless of method to correct for urine dilution or whether or not

adjustments were made for dilution. Bashash *et al.* (2017) excluded exposure outliers but found that doing so did not change the results in a meaningful way. Taken together, these studies suggest that urinary fluoride is a reasonable measure of exposure despite some of the potential issues.

A frequent critical limitation among the higher risk-of-bias studies was lack of information regarding exposure or poor exposure characterization. Many of the higher risk-of-bias studies only compared subjects living in two regions with differing levels of fluoride exposure, and while most of them did provide some differentiation in levels of fluoride between the areas, limited or no individual exposure information was reported. Among studies that provided drinking water levels of fluoride in two areas being compared, sufficient information to determine if the individual study subjects were exposed to these levels was often not reported. Some studies also lacked information on fluoride analysis methods and timing of the exposure measurements. In some cases ($n = 3$), study areas that were considered endemic for dental and/or skeletal fluorosis were compared to non-endemic areas, or high-fluoride areas were compared to low-fluoride areas, with no other information provided on fluoride levels in the areas (Sun *et al.* 1991, Li *et al.* 2003 [translated in Li *et al.* 2008c], Ren *et al.* 1989 [translated in Ren *et al.* 2008]). While living in an area endemic for fluorosis could be an indicator of exposure, these studies did not specify if the study subjects themselves had fluorosis. Another study used only dental fluorosis as a measure of fluoride exposure in subjects that were all from an endemic area with similar drinking water fluoride levels (Li *et al.* 2010).

Outcome assessment

Studies included in this evaluation used a wide variety of methods to measure IQ and other cognitive effects. Measures of IQ were generally standardized tests of IQ; however, for these standardized methods to be considered low potential for bias they needed to be conducted in the appropriate population or modified for the study population. Because results of these tests can be subjective, it was important that the outcome assessors were blind to the fluoride exposure when evaluating the results of the tests. If the study reported that the assessor was blind to the exposure, this was assumed to mean that the outcome assessor did not have any knowledge of the exposure, including whether the study subjects were from high-fluoride communities.

The lower risk-of-bias studies have few concerns regarding outcome assessment. Four studies (Barberio *et al.* 2017b, Riddell *et al.* 2019, Sudhir *et al.* 2009, Wang *et al.* 2020a) had concerns for potential bias in the outcome assessment and that was due to either the use of self-reported of outcomes or the lack of accounting for blinding at the time of the outcome assessment in cases where there was potential concern. The remainder of the studies used appropriate measures of IQ or other cognitive effects for the study population. Seventeen of the studies reported blinding of the outcome assessors or correspondence with the study authors indicated that it was not likely an issue. For the remainder of the studies, it was assumed that the outcome assessors were most likely blind because exposure was assessed via urine or drinking water obtained at the same time as the outcome assessment.

Among the studies with higher risk of bias, the main limitation in the outcome assessment was the lack of reporting on whether the outcome was assessed without knowledge of exposure. Although there is little concern that the children's knowledge of their own exposure would bias the way they took the IQ tests, there is potential for bias if the tests were administered by an interviewer, or if the scoring of results could be subjective (e.g., drawing tests), and the interviewer or scorer had knowledge of the children's exposure. Most of the studies did not provide sufficient information on the person scoring or administering the tests or other information on the assessment methods to alleviate concerns for potential interviewer or reviewer bias. In some cases, the outcomes were not considered sensitive

measures (e.g., Seguin Form Board Test to test for IQ), or the test was not considered appropriate for the study population (e.g., a test validated in a western population was used on a rural Chinese population).

IQ in Children

The results from 17 studies (3 prospective cohort and 14 cross-sectional studies from 13 different study populations) with lower potential for bias that evaluated IQ in children (Bashash *et al.* 2017, Choi *et al.* 2015, Ding *et al.* 2011, Rocha-Amador *et al.* 2007, Saxena *et al.* 2012, Seraj *et al.* 2012, Xiang *et al.* 2003a, Xiang *et al.* 2011, Zhang *et al.* 2015b, Yu *et al.* 2018, Green *et al.* 2019, Cui *et al.* 2018, Wang *et al.* 2020b, Wang *et al.* 2012, Sudhir *et al.* 2009, Till *et al.* 2020, Trivedi *et al.* 2012) provide consistent evidence that exposure to fluoride is associated with lower IQ scores (see [Figure D1](#) through [Figure D7](#)); however, the analyses performed and the specific results varied by study. Consistent results between increased fluoride levels and lower IQ scores were seen across studies using different exposure measures [e.g., single serum samples (Xiang *et al.* 2011, Zhang *et al.* 2015b), single spot urine samples in children (Xiang *et al.* 2003a, Rocha-Amador *et al.* 2007, Ding *et al.* 2011, Saxena *et al.* 2012, Zhang *et al.* 2015b, Cui *et al.* 2018, Yu *et al.* 2018, Wang *et al.* 2020b), and prenatal maternal urinary measures (Bashash *et al.* 2017, Green *et al.* 2019)] (see [Figure D6](#) and [Figure D7](#)). The consistency also occurs across different study designs and study populations. There were two studies with lower potential for bias (Cui *et al.* 2020, Soto-Barreras *et al.* 2019) that did not provide evidence of an association between fluoride exposure and IQ, but evaluating the association between fluoride and IQ levels was not the primary focus in either of these studies.

The three prospective cohort studies all found an association between increasing fluoride exposure and lower IQ in children. Two of the studies (Green *et al.* 2019, Till *et al.* 2020) were based on the same study population but evaluated fluoride exposure differently. Bashash *et al.* (2017) observed a significant inverse association between children's IQ and maternal urinary fluoride during pregnancy (measured during all three trimesters and included if at least one measurement was available; an increase of 0.5 mg/L of maternal urinary fluoride was associated with a 2.5-point lower IQ score [95% CI: -4.12, -0.59]) in boys and girls combined (see [Figure D7](#)); however, the association between IQ level and children's urinary fluoride levels, while inverse, was not significant (single spot urine sample; an increase of 0.5 mg/L of child urinary fluoride was associated with a 0.89-point lower IQ score [95% CI: -2.63, 0.85]) (Bashash *et al.* 2017). Green *et al.* (2019) also observed a significantly lower IQ for boys associated with maternal urinary fluoride averaged across trimesters (a significant 4.49-point lower IQ score [95% CI: -8.38, -0.60] in IQ per 1-mg/L increase in maternal urinary fluoride); results were not significant in girls (2.40-point increase [95% CI: -2.53, 7.33] in IQ) or in boys and girls combined (1.95-point lower IQ score per 1-mg/L increase; 95% CI: -5.19, 1.28). Other measures of prenatal exposure (maternal fluoride intake or water fluoride concentrations) were associated with lower IQ scores in boys and girls combined although the authors did not report boys and girls separately, as they found no significant effect measure modification between child sex and fluoride exposure in these analyses (Green *et al.* 2019). Specifically, when evaluating the association between estimated maternal fluoride intake based on maternal water and beverage consumption during pregnancy and IQ in children, a 1-mg increase in daily maternal consumption of fluoride during pregnancy was associated with a significantly lower IQ score of 3.66 points in boys and girls combined (95% CI: -7.16, -0.15). Similarly, water fluoride concentrations for pregnant women from fluoridated areas (mean water fluoride levels of 0.59 ± 0.08 mg/L) versus pregnant women from non-fluoridated areas (mean water fluoride levels of 0.13 ± 0.06 mg/L) were associated with a significant 5.29-point lower IQ score per 1-mg/L increase in fluoride in both boys and girls combined (95% CI: -10.39, -0.19) (Green *et al.* 2019). Using the same study population as Green *et al.* (2019), but using fluoride intake from formula or water concentrations in

formula-fed versus breastfed infants, Till *et al.* (2020) observed a significantly lower performance IQ scores regardless of the comparison used. They did not observe any effect on verbal IQ, and full-scale IQ was only significantly lower in formula-fed infants using water fluoride concentrations as the exposure measure. All other comparisons showed negative associations but were not significant.

Cross-sectional studies also demonstrated a consistent association between fluoride and lower IQ scores. Rocha-Amador *et al.* (2007) observed significant negative correlations between IQ and both water and children's single spot urinary fluoride levels in a population in Mexico (adjusted $\beta = -10.2$ per log fluoride increase [CIs not reported] and -16.9 per log fluoride increase [CIs not reported], respectively) (see [Figure D7](#)). The authors also observed a significant inverse association between IQ and children's drinking water and single spot urinary arsenic levels (adjusted $\beta = -6.15$ [CIs not reported] and -5.72 [CIs not reported], respectively). Because fluoride and arsenic were highly correlated in the study area, the authors were not able to adjust for exposure to arsenic when evaluating the effects of fluoride exposure (Rocha-Amador *et al.* 2007). Ding *et al.* (2011) reported a negative dose-response relationship between children's single spot urinary fluoride levels and IQ (see [Figure D4](#)); after adjusting for age, using multiple linear regression, they found a 0.59-point lower IQ score (95% CI: $-1.09, -0.08$) per 1-mg/L increase in urinary fluoride (p -value < 0.0001) (see [Figure D7](#)). Cui *et al.* (2018) observed a significant association between log-transformed children's single spot urine fluoride and lower IQ scores (2.47-point lower IQ scores [95% CI: $-4.93, -0.01$] per unit increase in urinary fluoride), and the association was the strongest in subjects with the TT polymorphism in the dopamine receptor D2 gene which, according to the authors, probably results in a reduced D2 receptor density (12.31-point lower IQ score [95% CI: $-18.69, -5.94$] per unit increase in urinary fluoride) (Cui *et al.* 2018).

Although Green *et al.* (2019) observed a significant negative association between maternal fluoride levels and IQ scores in boys but not girls in a Canadian population, sex differences were not observed in a cross-sectional study conducted using children spot urine fluoride concentrations in China (Wang *et al.* 2020b). Wang *et al.* (2020b) evaluated boys and girls combined and separately and observed significant decreasing trends in the sexes both combined and alone by urinary fluoride quartiles. When evaluated as a continuous variable, spot urinary fluoride levels (per 1-mg/L increase) were significantly associated with lower IQ scores in both girls (-1.379 [95%CI: $-2.628, -0.129$]) and boys (-1.037 [95% CI: $-2.040, -0.035$]), as well as, combined (-1.214 [95%CI: $-1.987, -0.442$]). Green *et al.* (2019) did not find any sex difference when using water fluoride concentrations, but Wang *et al.* (2020b) found that based on water fluoride quartiles there was a significant trend in girls and in boys and girls combined but not in boys alone. While there was a decreasing trend in boys, the results did not achieve statistical significance ($p = 0.077$). However, when water fluoride levels were evaluated as a continuous variable (per 1 mg/L increase), there were significant associations between lower IQ scores in both girls (-1.649 [95%CI: $-3.201, -0.097$]) and boys (-1.422 [95%CI: $-2.792, -0.053$]), as well as, combined (-1.587 [95%CI: $-2.607, -0.568$]).

Other cross-sectional studies also observed consistent results across populations, but there were some slight variations based on exposure measurement, level of exposure, or based on the outcome measured. Choi *et al.* (2015) conducted a pilot study with 51 children in an area of China with a wide range of fluoride concentrations in the drinking water. Aside from observing no association between the square root block design test score and fluoride exposure from drinking water, the authors observed consistent negative associations between IQ measures and fluoride in children's single spot urine or drinking water and significant associations between specific tasks from an omnibus IQ test (i.e., significantly lower WISC-IV backward and total digit span scores) and fluoride exposure based on moderate or severe dental fluorosis in children (see [Figure D7](#)). While observing no association between

IQ and low children's single spot urinary fluoride levels (0.01–1.60 mg/L), Yu *et al.* (2018) observed significant negative associations (p values not reported) between IQ and median children's urinary fluoride levels (1.60–2.50 mg/L)—with an IQ score 2.67 points lower (95% CI: –4.67, –0.68) for every 0.5-mg/L increment of urinary fluoride—and high children's urinary fluoride levels at 2.50–5.54 mg/L with an IQ score of 0.84 points lower (95% CI: –2.18, 0.50) for every 0.5-mg/L increment of urinary fluoride (see [Figure D7](#)). The authors also reported a significant negative association between drinking water fluoride levels at 3.40–3.90 mg/L (4.29-point lower IQ score [95% CI: –8.09, –0.48] for every 0.5-mg/L increment of water fluoride); a 0.04-point lower IQ score (95% CI: –0.33, 0.24) was observed for 0.5-mg/L increments of water fluoride at levels of 0.20–3.40 mg/L. When comparing water fluoride concentrations of >1 mg/L to ≤1 mg/L, there was an increased risk (adjusted OR = 1.25; 95% CI: 0.69, 2.26) for marginal intelligence (i.e., IQ score = 70–79) and a decreased risk (adjusted OR = 0.47; 95% CI: 0.32, 0.71) of excellent intelligence (i.e., IQ score ≥ 130) (see [Figure D4](#)). Similar results were observed using children's urinary fluoride levels (adjusted OR for marginal intelligence = 1.44; 95% CI: 0.72, 2.91; adjusted OR for excellent intelligence = 0.49; 95% CI: 0.26, 0.93) (Yu *et al.* 2018).

Two lower risk-of-bias studies (Cui *et al.* 2020, Soto-Barreras *et al.* 2019) did not observe a significant association between fluoride and IQ in children; however, both studies only performed simple comparisons between IQ and fluoride exposure. Cui *et al.* (2020) studied children in the same region as Cui *et al.* (2018)—and possibly included some of the same subjects but over a longer timeframe—and did not observe a significant change in IQ score with increasing urinary fluoride levels. Although there was a 2-point drop in IQ between the lowest fluoride exposure group (i.e., spot urine fluoride < 1.6 mg/L) and the highest fluoride exposure group (i.e., ≥ 2.5 mg/L), the difference in IQ (112.16 ± 11.50 versus 110.00 ± 14.92) was not significant (p = 0.58). However, this study did not account for age in the analysis, even though they reported a significant difference in IQ score based on age (p < 0.001). Soto-Barreras *et al.* (2019) also did not find an association between various fluoride exposure metrics (water, spot urine, exposure dose, and fluorosis index) and IQ grade. However, this study only compared fluoride exposure levels within the 5 IQ grades and did not adjust for any potential confounders.

The results from 47 studies with higher potential for bias that evaluated IQ in children provide consistent supporting evidence of decrements in IQ associated with exposures to fluoride. Forty-one of the 47 studies reported an association between high fluoride exposure and lower IQ scores in children.

Meta-analysis

In response to the recommendations of the NASEM review of the September 6, 2019 draft monograph (NASEM 2020), a two-part meta-analysis was conducted. The first part was an update to two previous meta-analyses (Choi *et al.* 2012, Duan *et al.* 2018) of group-level exposures from studies that reported a comparison of the mean IQ score between two or more exposure groups. The second part was a new meta-analysis and included studies with more precise individual-level exposures (e.g., urine, water, fluoride intake). The meta-analysis protocol can be found with the revised systematic review protocol posted in September 2020 (<https://ntp.niehs.nih.gov/go/785076>).

Group-level exposures

For the group-level exposure meta-analysis, a comparison on the mean outcome measure (IQ score) was conducted across two exposure groups (“exposed” and “reference”). If there were more than two exposure groups, the highest exposure group was designated the exposed group and the lowest exposure group was designated the reference group. For studies that had more than one exposed group (n = 17), a sensitivity analysis was performed to evaluate the impact of using any exposed group compared to the reference group. Using mean IQ levels with measures of uncertainty (95% confidence

interval [CI], standard error [SE], and sample size [N]) for exposed versus reference groups, the standardized mean difference (SMD) and corresponding 95% CI were calculated for each study. Given the heterogeneity of the studies, random effects models were used to obtain the pooled effect estimate, calculated as a weighted SMD with a corresponding 95% CI. These methods are consistent with both the Choi *et al.* (2012) and Duan *et al.* (2018) meta-analyses. More detailed methods are provided in [Appendix 5](#) and in the meta-analysis protocol, which can be found with the revised systematic review protocol posted in September 2020 (<https://ntp.niehs.nih.gov/go/785076>).

Characteristics of the 46 studies that compared mean IQ scores between groups of children with different levels of fluoride exposure are shown in [Table A-1](#). One study was conducted in New Zealand, 1 study was conducted in Mexico, 4 studies were conducted in Iran, 9 studies were conducted in India, and the remaining 31 studies were performed in China ([Table A-1](#)). Five study populations were exposed to fluoride from coal burning (Guo *et al.* 1991 [translated in Guo *et al.* 2008a], Li *et al.* 1994 [translated in Li *et al.* 2008b], Li *et al.* 1995, Li *et al.* 2009, Bai *et al.* 2014); otherwise, it is assumed that study populations were exposed to fluoride through drinking water. Measures of fluoride exposure included water fluoride ($n = 28$), dental fluorosis ($n = 7$), and other non-drinking water sources of exposure to fluoride (e.g., fluoride exposure from coal burning [$n = 11$]). Thirteen studies presented results for males and 12 studies reported results for females; 9 studies examined children < 10 years old and 11 studies examined children ≥ 10 years old. The CRT-RC was used to measure children's IQ in 23 studies. Other measures of IQ included Wechsler intelligence tests (Ren *et al.* 1989 [translated in Ren *et al.* 2008], Wang *et al.* 1996 [translated in Wang *et al.* 2008b], An *et al.* 1992, Broadbent *et al.* 2015), the Binet IQ test (Guo *et al.* 1991 [translated in Guo *et al.* 2008a], Xu *et al.* 1994), the Raven's test (Yao 1997, Yao *et al.* 1996, Seraj *et al.* 2006, Seraj *et al.* 2012, Eswar *et al.* 2011, Poureslami *et al.* 2011, Shivaprakash *et al.* 2011, Khan *et al.* 2015, Sebastian and Sunitha 2015, Mondal *et al.* 2016), the Raymond B Cattell test (Karimzade *et al.* 2014), the Japan IQ test (Sun *et al.* 1991, Zhang *et al.* 1998), the Index of Mental Capacity (Li *et al.* 1994 [translated in Li *et al.* 2008b]), the Sequin Form Board test (Nagarajappa *et al.* 2013), and other tests using a doctor-prepared questionnaire (Trivedi *et al.* 2012, Trivedi *et al.* 2007). This meta-analysis includes 27 studies that were also included in Choi *et al.* (2012) and 25 studies that were also included in Duan *et al.* (2018). Also included in this meta-analysis were an additional 3 studies published since the Duan *et al.* (2018) publication and 11 studies that were not captured in either of the previous meta-analyses. Overall, the updated group-level results were highly consistent with these previous meta-analyses (Choi *et al.* 2012, Duan *et al.* 2018) ([Table A5-1](#)).

The random-effects pooled SMD estimated from the 46 studies included in the meta-analysis was -0.50 (95% CI: $-0.61, -0.39$) ([Table A5-1](#), [Figure A5-1](#)). There was evidence of heterogeneity ($I^2 = 89\%$, $p < 0.001$, [Table A5-1](#)) and publication bias (funnel plot and Egger's $p < 0.001$, Begg's $p = 0.08$; [Figure A5-2](#), [Figure A5-3](#)). Eliminating publication bias through trim-and-fill analysis supports the results with an adjusted pooled effect estimate of -0.42 (95% CI: $-0.54, 0.30$) ([Figure A5-4](#)). Among the 46 studies, all but two showed SMD estimates that indicated an inverse association, ranging from -5.34 (95% CI: $-6.34, -4.34$) to -0.04 (95% CI: $-0.45, 0.36$). The studies with a positive association (Broadbent *et al.* 2015) reported an SMD estimate of 0.01 (95% CI: $-0.19, 0.22$) to 0.13 (95% CI: $-0.16, 0.42$). Three studies (Aravind *et al.* 2016, Kundu *et al.* 2015, Razdan *et al.* 2017) were excluded from the main analysis due to uncertainties about the way the intelligence assessment for children was performed, but sensitivity analyses that included these studies did not reveal any substantial changes in the pooled SMD estimate (-0.57 [95% CI: $-0.69, -0.45$]) (see [Figure A-35](#)).

Several subgroup analyses, discussed in [Appendix 5](#) and outlined in the meta-analysis protocol (found with the revised systematic review protocol posted in September 2020

[<https://ntp.niehs.nih.gov/go/785076>], included risk of bias, gender, age group, country, outcome assessment type, and exposure assessment type. Among the lower risk-of-bias studies ($n = 9$), the random-effects pooled SMD was -0.31 (95% CI: $-0.52, -0.10$) with an I^2 of 87% and heterogeneity test p -value < 0.001 (Table A5-1 and Figure A5-6). There was no evidence of publication bias (funnel plot and Egger's $p = 0.72$, Figure A5-7 and Figure A5-8). Among the higher risk-of-bias studies ($n = 37$), the random-effects pooled SMD was -0.56 (95% CI: $-0.68, -0.43$) with an I^2 of 88% and heterogeneity test p -value < 0.001 (Table A5-1 and Figure A5-6). There was evidence of publication bias among the higher risk-of-bias studies (funnel plot and Egger's $p < 0.001$, Figure A5-7 and Figure A5-8); eliminating publication bias through trim-and-fill analysis supports the results with an adjusted pooled SMD estimate of -0.35 (95% CI: $-0.50, -0.21$) (Figure A5-7 and Figure A5-9).

Subgroup analyses by gender, age group, country, outcome assessment type, and exposure assessment type further support the consistent and robust pattern of results (Table A5-1). Except for the subgroup analysis of the four studies from Iran, heterogeneity remained at an I^2 of $\geq 70\%$ when the analyses were restricted by subgroup. Sensitivity analyses that removed an outlier (Khan *et al.* 2015) or compared all exposed groups versus the reference (i.e., exposed groups were combined if a study reported more than one exposed group) also did not appreciably change the results (Figure A-45, Table A5-1, and Figure A-25).

Individual-level exposures

The individual-level exposure meta-analysis included 6 studies with individual-level exposures that reported effect estimates as beta coefficients and included a 95% CI or SE. Characteristics of the studies with individual-level exposures are shown on Table B-1. All studies included in this meta-analysis were considered lower risk of bias. Adjusted effect estimates were used, and if results from multiple models were reported within a single study, the most adjusted results were selected. (For more details, see the meta-analysis protocol, which can be found with the revised systematic review protocol posted in September 2020 [<https://ntp.niehs.nih.gov/go/785076>].) To ensure consistent units across studies, units of fluoride exposure were transformed to 1 mg/L. For Bashash *et al.* (2017), Yu *et al.* (2018), and Till *et al.* (2020), units of exposure were transformed from 0.5 mg/L to 1 mg/L. For Cui *et al.* (2018), units of exposure were transformed from 1 log mg/L to 1 mg/L. Cui *et al.* (2018) reported an association between IQ and log transformed exposure. A sensitivity analysis was performed to evaluate the impact of using Cui *et al.* (2018), since the relationship between IQ and exposure evaluated in this study was not linear (as was the case among the other studies included). Yu *et al.* (2018) reported estimates from piecewise linear regression models and provided three ranges for urinary fluoride exposure (low 0.01–1.60 mg/L, medium 1.60–2.50 mg/L, high 2.50–5.54 mg/L) and two ranges for water fluoride (low 0.20–3.40 mg/L and high 3.40–3.90 mg/L). Since these piecewise effect estimates are likely correlated, the study-specific pooled effect estimates were used for urine and water fluoride exposures for the overall effect meta-analysis. A sensitivity analysis was performed to evaluate the impact of using pooled estimates rather than piecewise estimates from Yu *et al.* (2018).

For studies with overlapping populations (i.e., multiple studies that used the same cohort), results were selected considering the following factors: most appropriate exposure metric, exposure range, exposure period, number of subjects, and statistical adjustment for potential confounders. In the overall effect analysis, for studies reporting multiple measures of fluoride exposure, the results associated with measured or estimated individual-level exposures, biomarker levels (such as urinary fluoride), or fluoride intake levels were prioritized over water fluoride concentrations (revised protocol posted in September 2020 [<https://ntp.niehs.nih.gov/go/785076>]); however, subgroup analyses by exposure metric (urinary fluoride, fluoride intake, and water fluoride) were also performed. Yu *et al.* (2018) and

Wang *et al.* (2020b) used the same study cohort of children recruited in 2015 from the rural areas of Tianjin City, China. Since Wang *et al.* (2020b) ($n = 571$) used a subset of the original study sample from Yu *et al.* (2018) ($n = 2,668$), only results from Yu *et al.* (2018) were included in the meta-analysis. A sensitivity analysis was performed to evaluate the impact of using the effect estimate from Wang *et al.* (2020b) rather than the pooled effect estimate from Yu *et al.* (2018). Green *et al.* (2019) and Till *et al.* (2020) used the same Maternal-Infant Research on Environmental Chemicals (MIREC) cohort that reported drinking tap water in 10 Canadian cities with the studies overlapping for 398 mother-child pairs. Both studies reported effect estimates for maternal urinary fluoride (MUF) and water fluoride concentrations. In the Green *et al.* (2019) study, 512 mother-child pairs had MUF data (and all covariates) compared to 398 pairs in Till *et al.* (2020). Water fluoride levels were available for 420 pairs in Green *et al.* (2019) compared to 398 pairs in Till *et al.* (2020). Both studies reported effect estimates adjusted for maternal education, maternal race, child's sex, HOME total score, and secondhand smoke status in the child's home. In addition, Till *et al.* (2020) adjusted for child's age at IQ testing (the age range for all children was 3–4 years old). Because of the larger sample size and covariate adjustments were similar, results from Green *et al.* (2019) were included in the main analysis. However, because of the more adjusted estimates from Till *et al.* (2020) compared to Green *et al.* (2019), a sensitivity analysis was performed using the water fluoride result for formula-fed children and the MUF result from Till *et al.* (2020). For fluoride from intake, the estimates from both studies were used since they represent total fluoride intake (Green *et al.* 2019) and infant fluoride intake from formula (Till *et al.* 2020).

The overall pooled effect estimate based on 6 lower risk-of-bias studies with individual-level measures of exposure shows that a 1-mg/L increase in urinary fluoride was associated with a statistically significant lower IQ score of 1.40 (95% CI: $-2.33, -0.47$) points. Studies with individual-level urinary fluoride measures had evidence of moderate heterogeneity ($I^2 = 46\%$, $p = 0.101$; [Table A5-2](#), [Figure A5-16](#)). Eliminating publication bias through trim-and-fill analysis supports the conclusion that a 1-mg/L increase in individual-level exposure to urinary fluoride was associated with lower IQ, with an adjusted pooled effect estimate of -0.82 (95% CI: $-1.81, 0.17$) ([Figure A5-19](#)). Fluoride intake and water fluoride were also significantly associated with an IQ score of 3.31 points lower (95% CI: $-6.12, -0.50$) and 4.77 points lower (95% CI: $-9.10, -0.45$), respectively ([Table A5-2](#)); however, the results for both metrics were based on two studies each and should be interpreted with caution.

No substantial changes in the pooled effect estimates were seen in sensitivity analyses to evaluate the following scenarios: using the piecewise estimates from Yu *et al.* (2018) (-1.37 , 95% CI: $-2.38, -0.37$) ([B-1](#)); using effect estimates from Wang *et al.* (2020b) rather than Yu *et al.* (2018) (-1.24 , 95% CI: $-1.94, -0.54$) ([Figure B-6](#)); and using the water fluoride result for formula-fed children and MUF result from Till *et al.* (2020) rather than effect estimates from Green *et al.* (2019) (-1.50 , 95% CI: $-2.44, -0.57$) ([Figure B-11](#)).

Other Neurodevelopmental or Cognitive Effects in Children

Among the studies with lower potential for bias, the results from three prospective cohort studies (Bashash *et al.* 2017, Valdez Jimenez *et al.* 2017, Bashash *et al.* 2018) and six cross-sectional studies (Li *et al.* 2004 [translated in Li *et al.* 2008a], Rocha-Amador *et al.* 2009, Choi *et al.* 2015, Barberio *et al.* 2017b, Wang *et al.* 2020a, Riddell *et al.* 2019) based on seven study populations provide mostly consistent results for associations of fluoride exposure with cognitive impairment in children other than decrements in IQ, such as hand-eye coordination, neurobehavioral assessment, behavioral capacity, and learning disabilities (see [Figure D8](#) through [Figure D10](#)). Because IQ cannot be assessed in infants, other neurodevelopmental tests were conducted. Two studies (Li *et al.* 2004 [translated in Li *et al.* 2008a],

Valdez Jimenez *et al.* 2017), based in China and Mexico, evaluated neonates (within 3 days of birth) or infants (3–15 months) (see [Figure D8](#) and [Figure D10](#)).

In neonates, the high fluoride group (based on a single maternal urine fluoride level just prior to birth [3.58 ± 1.47 mg/L] compared to controls [1.74 ± 0.96 mg/L]) had significant lower ($p < 0.05$) total neurobehavioral assessment scores (38.28 ± 1.10 in controls compared to 36.48 ± 1.09 in high fluoride group) and total behavioral capacity scores (11.34 ± 0.56 in controls compared to 10.05 ± 0.94 in high fluoride group) as measured by a standard neonatal behavioral neurological assessment (NBNA) method (Li *et al.* 2004 [translated in Li *et al.* 2008a]). In infants, the Mental Development Index (MDI)—which measures functions including hand-eye coordination, manipulation, understanding of object relations, imitation and early language development—was significantly negatively correlated with maternal urinary fluoride in both the first and second trimesters (adjusted β s = -19.05 with standard error of 8.9 for first trimester and -19.34 with standard error of 7.46 for second trimester) (Valdez Jimenez *et al.* 2017). This study did not find an association between maternal fluoride during any trimester and Psychomotor Developmental Index (PDI), which measures gross motor development (adjusted β s = 6.28 and 5.33 for first and second trimesters, respectively; no variance provided) (Valdez Jimenez *et al.* 2017). The General Cognitive Index (GCI) of the McCarthy Scales of Children's Abilities (MSCA) in 4-year-old children was significantly negatively associated with maternal creatinine-adjusted urinary fluoride levels during pregnancy (collected during each trimester) even after adjusting for maternal bone lead (adjusted β = -3.15 [95% CI: -5.42 , -0.87] in a model adjusting for main covariates (e.g., gestational age, weight at birth, sex, maternal smoking, and indicators of socioeconomic status); adjusted β = -5.63 [95% CI: -8.53 , -2.72] in a model limited to a subset of cases who had data on maternal bone lead and adjusted for main covariates and maternal bone lead) (Bashash *et al.* 2017) (see [Figure D10](#)). Choi *et al.* (2015), however, evaluated cognitive function endpoints in addition to IQ and found no significant associations between concurrent water or urinary fluoride levels and Wide Range Assessment of Visual Motor Ability (WRAVMA) scores, finger tapping, and the grooved pegboard test although there were some significant associations based on degree of fluorosis (see [Figure D10](#)). Another study using construction and memory scores in children 6–11 years old observed statistically significant lower scores with increasing concurrent child single spot urinary fluoride even after adjusting for age ($p < 0.05$; -0.29 and -0.27 for copy and immediate recall, respectively [CIs not reported]); however, scores were not significantly associated with urinary arsenic levels (-0.05 and 0.02 for copy and immediate recall, respectively [CIs not reported]) (Rocha-Amador *et al.* 2009) (see [Figure D9](#)).

Barberio *et al.* (2017b) evaluated learning disabilities in children 3–12 years of age, including ADHD, attention deficit disorder (ADD), and dyslexia, as part of the Canadian Health Measures Survey and found a small but significantly increased risk in self-reported (children 12 years of age) or parent- or guardian-reported (children 3–11 years of age) learning disabilities associated with higher spot urinary fluoride levels in children (adjusted OR = 1.02; 95% CI: 1.00, 1.03) (see [Figure D11](#)); however, significant associations were not observed in analyses using creatinine- or specific gravity-adjusted urinary fluoride (Barberio *et al.* 2017b). Barberio *et al.* (2017b) also reported no associations between single spot urinary fluoride and ADHD in children ages 3 to 12 years. Riddell *et al.* (2019) used the same Canadian Health Measured Survey, but evaluated children 6–17 years old. Riddell *et al.* (2019) found a significantly increased risk for ADHD diagnosis with both tap water fluoride (adjusted OR per 1-mg/L increase = 6.10; 95% CI: 1.60, 22.8) and community water fluoridation status (adjusted OR = 1.21; 95% CI: 1.03, 1.42). A similar increase in hyperactivity-inattention symptoms score based on the Strengths and Difficulties Questionnaire was observed with both tap water fluoride (adjusted β per 1-mg/L increase = 0.31; 95% CI: 0.04, 0.58) and community fluoridation status (adjusted β = 0.11; 95% CI: 0.02, 0.20). As was observed with Barberio *et al.* (2017b), Riddell *et al.* (2019) did not observe an association with either

ADHD diagnosis (adjusted OR per 1-mg/L increase = 0.96; 95% CI: 0.63, 1.46) or hyperactivity-inattention symptoms (adjusted β = 0.31; 95% CI: -0.04, 0.66) and specific-gravity-adjusted spot urinary fluoride concentrations. Bashash *et al.* (2018) evaluated behaviors associated with ADHD in children ages 6–12 years using the Conners' Rating Scales-Revised (CRS-R) and observed significant associations between maternal urinary fluoride (measured during each trimester) and ADHD-like symptoms, particularly those related to inattention (an increase in 0.5 mg/L of maternal urinary fluoride was associated with a 2.84-point increase [95% CI: 0.84, 4.84] in the DSM-IV Inattention Index and a 2.54-point increase [95% CI: 0.44, 4.63] in the Cognitive Problems and Inattention Index). These two scales contributed to the global ADHD Index and the DSM-IV ADHD Total Index, which were also associated with higher levels of prenatal fluoride exposure (an increase of 0.5 mg/L in maternal urinary fluoride was associated with a 2.38-point increase [95% CI: 0.42, 4.34] in the DSM-IV ADHD Total Index and a 2.47-point increase [95% CI: 0.43, 4.50] in the ADHD Index) (see [Figure D10](#)). Significant associations were not observed between maternal urinary fluoride concentrations during pregnancy and child performance on measures of hyperactivity nor were there any significant results in children using the Connors' Continuous Performance Test (CPT-II, 2nd Edition), a computerized test of sustained attention and inhibitory control (Bashash *et al.* 2018). Wang *et al.* (2020a) also used a Connors' Parent Rating Scale (Chinese version), but only found a significant association between spot urinary fluoride concentrations (model adjusted for creatinine) and psychosomatic problems (adjusted OR for T-score > 70 = 1.97; 95% CI: 1.19, 3.27 and adjusted β = 4.01; 95% CI: 2.74, 5.28). No associations were found between spot urinary fluoride and ADHD index or other behavioral measures.

Higher risk-of-bias studies (n = 5) also provide some evidence of associations of fluoride exposure with neurodevelopmental or cognitive effects in children other than effects on IQ, but the results are inconsistent with heterogeneous outcomes (Li *et al.* 1994 [translated in Li *et al.* 2008b], Shannon *et al.* 1986, Malin and Till 2015, Morgan *et al.* 1998, Mustafa *et al.* 2018).

Cognitive Effects in Adults

Results from two lower risk-of-bias studies in adults did not find consistent evidence for an association between cognitive impairment (based on the Mini-Mental State Examination) and exposure to fluoride (Jacqmin *et al.* 1994, Li *et al.* 2016). Jacqmin *et al.* (1994) did not find an association between drinking water fluoride and cognitive impairment in populations in France (n = 3,490) and found prevalence rates of cognitive impairment to be the same regardless of fluoride exposure (see [Figure D12](#)). In an analysis of 38 cognitively-impaired cases and 38 controls matched for several confounders including age, gender, education, alcohol consumption, and smoking, Li *et al.* (2016) did find significantly higher urinary fluoride levels and skeletal fluorosis scores in the cognitively-impaired group compared with the control group; however, the authors found no significant correlation between cognitive impairment and total daily water fluoride intake (adjusted ORs = 0.94 [95% CI: 0.85, 1.04] and 0.86 [95% CI: 0.69, 1.06] in the moderate and severe cognitive impairment groups, respectively) or urinary fluoride levels (adjusted ORs = 1.12 [95% CI: 0.89, 1.42] and 1.25 [95% CI: 0.87, 1.81] in the moderate and severe cognitive impairment groups, respectively) in subjects from fluorosis-endemic areas of China (n = 511).

Higher risk-of-bias studies (n = 7) provide some evidence of cognitive impairment in adults associated with exposure to fluoride. In aluminum factory workers (exposed to gaseous and particulate fluoride emissions during the production of aluminum metal), significant decreases in IQ (Duan *et al.* 1995), diminished performance on several neurobehavioral core battery tests (NCTBs) (Guo *et al.* 2001 [translated in Guo *et al.* 2008b]), and impaired psychomotor performance and memory were observed (Yazdi *et al.* 2011). One study conducted on adult subjects with fluorosis (dental and skeletal) from a fluorosis-endemic area compared with healthy subjects from a non-endemic area observed significant

differences for some cognitive function tests (i.e., tests of speech fluency, recognition, and working memory) but not others and generally did not observe a significant change in IQ except in the operation scores (Shao 2003). One prospective cohort study evaluated exposure to fluoride in children at age of 5 years based on whether or not the children resided in areas with community water fluoridation or used fluoride toothpaste or fluoride tablets, and found no clear differences in IQ scores of the subjects at age 38 years (Broadbent *et al.* 2015). One additional study suggested that populations living in areas with higher drinking water fluoride had lower levels of dementia (Still and Kelley 1980); however, the study was not focused on effects of fluoride, but rather if fluoride was able to reduce the risk associated with aluminum by competing with aluminum and reducing the aluminum bioavailability. Therefore, the study was considered inadequate to evaluate the effects of fluoride on dementia (Still and Kelley 1980). A more recent study in Scotland evaluated dementia rates associated with aluminum and fluoride drinking water concentrations and observed an increase in dementia only in the highest quartile of fluoride (56.3 µg/L) compared to the lowest quartile (<44.4 µg/L), but found a significant increase with all quartiles of aluminum compared with the reference group (Russ *et al.* 2019). In addition to studies that reported on cognitive impairment and exposure to fluoride, two studies were identified that reported effects on motor and sensory function (Rotton *et al.* 1982) and a higher prevalence of self-reported headaches, insomnia, and lethargy (Sharma *et al.* 2009).

Mechanistic Data in Humans

Eight lower risk-of-bias studies were available that evaluated mechanistic data in humans associated with fluoride exposure that was considered potentially relevant to neurological effects, including effects on thyroid hormones in children (Singh *et al.* 2014, Zhang *et al.* 2015b, Kumar *et al.* 2018), adults (Kheradpisheh *et al.* 2018b, Kheradpisheh *et al.* 2018a, Malin *et al.* 2018), or children and adults combined (Barberio *et al.* 2017a). In addition, some studies evaluated self-reported thyroid conditions in children and adults combined (Barberio *et al.* 2017a) and thyroid diseases in adults (Kheradpisheh *et al.* 2018b, Peckham *et al.* 2015) (see [Figure A3-5](#) and [Figure A3-6](#)). Although the lower risk-of-bias studies provide some evidence of mechanistic effects (primarily changes in thyroid stimulating hormone [TSH] levels in children), the studies were too heterogeneous or limited in number to make any determination on mechanism (see [Figure 7](#)).

Among the seven lower risk-of-bias studies that reported on changes in thyroid hormones, three studies were conducted in children (Zhang *et al.* 2015b, Singh *et al.* 2014, Kumar *et al.* 2018) and reported increases in TSH levels. Zhang *et al.* (2015b) reported significant increases in TSH in children from a fluorosis-endemic area (median fluoride drinking water concentration = 1.40 mg/L; interquartile range = 1.23–1.57 mg/L) compared with a non-fluorosis-endemic area (median fluoride drinking water concentration = 0.63 mg/L; interquartile range = 0.58–0.68 mg/L), while 3,5,3'-triiodothyronine (T₃) or thyroxine (T₄) were not significantly different between the two groups. Similarly, Singh *et al.* (2014) observed significantly higher TSH levels in children without dental fluorosis who lived in a fluorosis-endemic area (fluoride drinking water concentrations of 1.6–5.5 mg/L) compared with children without dental fluorosis who lived in a non-fluorosis-endemic area (fluoride drinking water concentrations of 0.98–1.00 mg/L). Higher TSH levels in children with dental fluorosis from the fluorosis-endemic area compared with children without dental fluorosis from the non-fluorosis-endemic area were observed but did not reach statistical significance. Significant differences in T₄ or T₃ were not observed between groups (Singh *et al.* 2014). Kumar *et al.* (2018) also observed a significant increase in TSH levels in children from a fluorosis endemic area (1.5–5.8 mg/L fluoride) compared with a control area (0.94–1.08 mg/L fluoride). There were also decreases in T₃ and T₄, but results were not statistically significant.

Barberio *et al.* (2017a) evaluated fluoride effects on TSH levels in children and adults combined and found no relationship between fluoride exposure (measures in urine and tap water) and TSH levels. In the one study that evaluated thyroid hormone levels in adults but not children, Kheradpisheh *et al.* (2018b) found a significant increase in TSH associated with higher fluoride concentrations in drinking water in both adults with and without thyroid diseases such as hypothyroidism, hyperthyroidism, thyroid nodules, or thyroid cancer. Significant increases in T₃ were associated with higher fluoride in drinking water in adults without thyroid diseases, but increases in T₃ were not significant in adults with thyroid diseases. A significant association between T₄ and higher fluoride in drinking water was not observed in adults with or without thyroid diseases (Kheradpisheh *et al.* 2018b).

Other than changes in hormone levels, there is limited evidence of fluoride-related mechanistic effects in the three lower risk-of-bias studies that evaluated thyroid-related effects. Barberio *et al.* (2017a) found no relationship between fluoride exposure and self-reported thyroid conditions in children and adults (children were older than 12). Kheradpisheh *et al.* (2018b) also found no association between fluoride exposure and hypothyroidism in an adult population in Iran. One study found a significantly higher prevalence of hypothyroidism in areas with higher fluoride concentrations in drinking water (>0.7 mg/L) compared with areas with lower fluoride drinking water concentrations (≤0.7 mg/L) (Peckham *et al.* 2015).

Several higher risk-of-bias studies were available that evaluated potential mechanistic data in humans associated with fluoride exposure, including effects on thyroid hormones mostly in children (n = 11 studies); catecholamines in adults (Michael *et al.* 1996) or in subjects of unknown ages (Chinoy and Narayana 1992); acetylcholinesterase (AChE) or serotonin levels in children (Singh *et al.* 2013, Lu *et al.* 2019); brain histopathology or biochemistry in aborted fetuses (Du *et al.* 1992 [translated in Du *et al.* 2008], Yu *et al.* 1996 [translated in Yu *et al.* 2008]); and mitochondrial fission/fusion molecules in children (Zhao *et al.* 2019). Similar to the lower risk-of-bias studies, the higher risk-of-bias studies provide some evidence of mechanistic effects (primarily changes in TSH levels in children); however, the data are insufficient to identify a clear mechanism by which fluoride causes neurodevelopmental or cognitive effects in humans.

Among higher risk-of-bias studies (see [Figure A3-7](#) and [Figure A3-8](#)), varying results were reported in 11 studies that evaluated fluoride exposure and effects on thyroid hormones, and a few of these studies (Lin *et al.* 1991, Yang *et al.* 1994 [translated in Yang *et al.* 2008], Wang *et al.* 2001) were complicated by high or low iodine in the high fluoride area. When considering fluoride effects on each of the hormones individually, similar to results from lower risk-of-bias studies, the most consistent evidence of fluoride-associated effects on a thyroid hormone was reported as changes in TSH levels in children, although there was some variation in the direction of effect. Six of the nine higher risk-of-bias studies that evaluated changes in TSH levels in children reported increases in TSH levels with higher fluoride (Lin *et al.* 1991, Susheela *et al.* 2005, Wang *et al.* 2001, Yang *et al.* 1994 [translated in Yang *et al.* 2008], Yao *et al.* 1996, Yasmin *et al.* 2013). Two of the nine higher risk-of-bias studies reported decreases in TSH levels in children with higher fluoride (Khandare *et al.* 2017, Khandare *et al.* 2018). One of the nine studies found no significant alterations in TSH levels in children from fluorosis-endemic areas (Hosur *et al.* 2012) (see [Figure 8](#)).

When considering fluoride-associated effects on TSH, T₃, and T₄ levels together, studies that evaluated changes in all three thyroid hormones reported varying combinations of increases, decreases, or no changes in levels across the three hormones, although among the eight lower and higher risk-of-bias studies that evaluated the effects of fluoride exposure on TSH, T₃, and T₄ levels and reported increases

in TSH levels in children, seven of the eight studies found no alterations in T₃ levels (one study found an increase in T₃), and six of the eight studies found no alterations in T₄ levels (two studies found an increase in T₄). Studies also displayed variation by age in fluoride-associated effects on TSH, T₃, and T₄. Due to the dynamic relationship between the thyroid gland, the pituitary gland, and the production and clearance of TSH, T₃, and T₄, the variations in results are not unexpected and do not eliminate the possibility of a mechanistic link between thyroid effects and neurodevelopmental or cognitive effects; however, the data do not support a clear indication that thyroid effects are a mechanism by which fluoride causes these effects in humans.

In addition to evaluating thyroid hormone levels, a few higher risk-of-bias studies evaluated other mechanistic data associated with fluoride exposure; however, the data are insufficient to identify a clear mechanism by which fluoride might cause neurodevelopmental or cognitive effects in humans. Serum epinephrine and norepinephrine were significantly increased in a fluoride-endemic region (not reported whether subjects were children or adults) compared to a non-endemic region (Chinoy and Narayana 1992). Serum adrenaline and noradrenaline were significantly increased in adults in a fluoride-endemic area (fluoride in the drinking water ranged from 1.0–6.53 ppm) compared to a control area (fluoride in the drinking water ranged from 0.56–0.72 ppm) (Michael *et al.* 1996). Serum AChE was significantly reduced in children from a high fluoride region compared to a lower fluoride region (Singh *et al.* 2013). Serum serotonin was significantly increased in children from Turkey who were drinking water containing 2.5 mg/L of fluoride compared to children drinking bottled water or water containing <0.5 mg/L of fluoride (Lu *et al.* 2019). Aborted fetuses from high fluoride areas in China were found to have histological changes in the brain and significant changes in neurotransmitter levels compared to a control area (Du *et al.* 1992 [translated in Du *et al.* 2008], Yu *et al.* 1996 [translated in Yu *et al.* 2008]).

There are also two more recent lower risk-of-bias studies that evaluated polymorphisms in dopamine-related genes; however, a determination on mechanism cannot be made at this time due to the limited number of studies. For children (10–12 years old) with a Val158Met polymorphism in the *COMT* gene (i.e., catechol-O-methyltransferase), which results in slower degradation and greater availability of dopamine within the brain, a stronger association between increasing urinary fluoride levels and decreasing IQ was reported (Zhang *et al.* 2015b). For children (7–12 years old) with a dopamine receptor-2 (DRD2) Taq 1A polymorphism (which is involved in reduced D2 receptor density and availability) and the TT (variant) genotype, a significant inverse relationship between log urine fluoride and IQ was observed; however, this significant relationship was not observed in children with the CC (wild-type) or CT (hybrid) genotypes (Cui *et al.* 2018).

Figure 7. Number of Lower Risk-of-bias Studies that Evaluated Thyroid Hormones in Children and Adults by Endpoint and Direction of Effect*

Endpoint	Direction of Effect		Grand Total
	↑	NS	
serum T3	1	3	4
serum T4		4	4
serum TSH	5	2	7
self-reported thyroid condition		1	1
thyroid disease		1	1
hypothyroidism prevalence	1		1

Animal Learning and Memory Data

[Note: An earlier version of the monograph underwent NASEM committee peer review in November 2019 (NASEM 2020). In this earlier review the committee criticized this section primarily over concerns that the NTP’s risk-of-bias evaluations failed to adequately capture a number of important threats to internal validity that are specific to neurobehavioral outcomes in animal tests. The committee found

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

several examples of studies cited in the monograph where national or international guidelines for performance or statistical analyses were not followed or descriptions of methods were insufficient to evaluate their adequacy. Additionally, the committee took issue with a conclusion of the prior peer reviewed systematic review of the experimental animal literature (NTP 2016) concerning the degree to which motor activity deficits might compromise neurobehavioral assessments, affecting the directness of applicability of deficits in animal learning and memory to support the plausibility of IQ deficits in exposed children.

The NTP generally does not take issue with the NASEM peer review comments and acknowledges that further efforts to disentangle the potential for motor activity deficits to influence tests of learning and memory in the fluoride literature are warranted. The NTP agrees with the comments of the NASEM committee concerning the overall poor quality of the experimental animal database, with many studies suffering from major reporting deficiencies. NTP also found these to be general issues with the experimental animal database and were identified as deficiencies that led to the inadequate conclusion. However, the following experimental animal study section remains largely unchanged from the initial version of the monograph reviewed by NASEM in November 2019. The reasons for this are: (1) because a more critical risk-of-bias assessment would result in fewer relevant animal studies judged to be of high quality; (2) because the highest quality experimental animal study reviewed for this monograph (McPherson *et al.* 2018) did not find effects of fluoride on learning, memory or motor activity in the critical ≤ 20 ppm in drinking water concentration range; and (3) because of the availability of a large number of human epidemiology studies directly addressing neurobehavioral and cognitive effects of fluoride in children, a decision was made to focus efforts to address comments on the critical human epidemiology evaluation in this revised and updated monograph. NTP acknowledges the helpful comments of the NASEM committee on the following section and refers readers to the NASEM review (NASEM 2020) when considering the information provided. For the purpose of this updated review the NTP considers that the experimental animal data remain *inadequate* to inform conclusions on whether fluoride exposure is associated with cognitive effects (including cognitive neurodevelopmental effects) in humans. NTP is aware of a number of additional relevant experimental animal studies published since the literature cutoff date for the monograph. These additional studies have not been formally reviewed and may shed further light on these issues].

In 2016, NTP conducted a systematic review of the available experimental animal studies to develop level-of-evidence conclusions on the association between fluoride exposure and neurobehavioral effects, specifically effects related to learning and memory impairment (NTP 2016). As previously discussed, the evaluation of the animal body of evidence in this assessment is an extension of the NTP (2016) systematic review and is consistent with the methodology and format used in that report.

NTP (2016) identified two main issues with the animal body of evidence related to effects of fluoride exposure on learning and memory: indirectness and concerns for risk of bias. The concern related to indirectness was based on the fact that many learning and memory tests rely on a motor response (e.g., latency to achieve the desired effect). Changes in motor function or activity levels associated with fluoride exposures could complicate the interpretation of the results on learning and memory test performance depending on the outcome measured. The directness of the measure as an indicator of learning and memory (i.e., the ability to rule out impaired motor or sensory function) was considered when addressing confidence in the data. Concerns in these studies related to risk of bias included the following factors: lack of randomization, lack of blinding or other methods to reduce potential bias at outcome, lack of exposure information, lack of control for litter effects, lack of expected response in the

control animals, and lack of reporting of other key study information such as sample size or sex of the animals.

Since the NTP (2016) report was published, additional experimental animal studies were identified that evaluated learning and memory impairment associated with fluoride exposure, including 12 developmental exposure studies (Banala and Karnati 2015, Mesram *et al.* 2016, Zhu *et al.* 2017, Sun *et al.* 2018, Wang *et al.* 2018, Ge *et al.* 2018b, McPherson *et al.* 2018, Zhao *et al.* 2019, Ge *et al.* 2018a, Chen *et al.* 2018, Bartos *et al.* 2018, Banala *et al.* 2018); 5 Morris water maze study in adults (Zheng *et al.* 2016, Niu *et al.* 2018, Dong *et al.* 2017, Sharma *et al.* 2018, Yang *et al.* 2018); and 7 other maze studies in adults (Pulungan *et al.* 2016, Shalini and Sharma 2015, Sharma *et al.* 2018, Sudhakar *et al.* 2017, Nageshwar *et al.* 2018, Yuan *et al.* 2019, Raju *et al.* 2019). In addition, 12 studies were identified that evaluated motor activity/coordination or sensory effects without evaluating learning and memory impairment (Adedara *et al.* 2017a, Nageshwar *et al.* 2017, Nkpaa and Onyeso 2018, Sudhakar *et al.* 2018b, Ahmad *et al.* 2017, Kinawy and Al-Eidan 2018, Manusha *et al.* 2019, Sudhakar *et al.* 2018a, Agustina *et al.* 2018, Lu *et al.* 2019, Jia *et al.* 2019, Li *et al.* 2019).

Although Adedara *et al.* (2017a) and Nkpaa and Onyeso (2018) evaluated exploration, the authors concluded that the track plots in the open field novel environment test were consistent with impaired locomotor activity in the fluoride-treated animals. The additional studies reviewed did not address the concern of indirectness and most included risk-of-bias concerns; however, a few of these more recent studies are notable in that they provide results on learning and memory effects that could possibly be distinguished from effects on motor activity. Bartos *et al.* (2018) used a step-down inhibitory avoidance test to evaluate short-term and long-term memory in rat offspring. Although the authors did not discuss activity in the animals, this test would be expected to result in increased latency in animals if there was decreased activity with fluoride exposure. The fluoride-treated female offspring, however, had decreased latency indicating diminished memory of the foot shock. Chen *et al.* (2018) also evaluated female rat offspring (treatment continued until the offspring were 6 months old) and observed an effect of fluoride on latency to reach the platform and the number of platform crossings in the Morris Water Maze; however, swimming speed was measured, and no changes were observed. The tracks during the spatial probe test were also very different in the two higher exposed groups (i.e., 50 and 100 mg/L NaF), suggesting that the animals did not know the location of the platform. It is not clear if litter effects were addressed in the study.

After further evaluation of the data available in NTP (2016) and in this update, it is concluded that the animal data are inadequate to evaluate the effects of fluoride on learning and memory primarily due to the inability to separate the learning and memory effects from the effects on motor activity or motor coordination. The majority of the studies that evaluated effects of fluoride on learning and memory did not also evaluate a motor activity component to determine if the learning and memory effects could be attributed to motor activity or coordination deficits. Of the studies that did evaluate both learning and memory and motor activity/coordination, studies mainly found an association between fluoride exposure and both types of neurological outcomes or found no effect of fluoride exposure on either type of neurological outcome irrespective of the dose range or duration of dosing. In addition, studies that found effects on motor activity/coordination or learning and memory often did not provide sufficient indicators of general health of the animals to reliably attribute impaired performance on a task to a specific acquisition of learning and memory or motor activity/coordination. The few studies that provided this information used different test methods or results were inconsistent. Thus, it is difficult to conclude that evidence from experimental animal studies is meaningful when considering the specific question of fluoride's potential influence on human IQ or cognitive function, particularly at

human -relevant exposure levels. Based on this consideration, the experimental animal body of evidence does not contribute to confidence in conclusions derived from human epidemiological studies with respect to effects on human IQ. Although the evidence supports an association between fluoride exposure and neurodevelopmental effects, the data are not sufficient to support the primary effect evaluated in children (i.e., IQ) nor is it sufficient to support a conclusion on cognitive effects in adults especially in the absence of additional adult human data.

Mechanistic Data in Animals

There are a wide variety of studies in animals that evaluate mechanistic effects potentially related to neurological changes following oral fluoride exposure (see [Figure 9](#)). Categories of mechanistic endpoints with the largest amount of available data include changes in biochemical components of the brain or neurons, neurotransmitters, oxidative stress, histopathology, and thyroid function. Limiting the data to studies with at least one exposure at or below 20 ppm fluoride drinking water equivalents (gavage and dietary exposures were back calculated into equivalent drinking water concentrations for comparison) still provided a sufficient number of studies for evaluation of these mechanistic endpoints. Neurotransmitter and biochemical changes in the brain and neurons were considered to be the mechanistic areas with the greatest potential to demonstrate effects of fluoride on the brain of animals in the lower dose range and provide evidence of changes in the brain that may relate to lower IQ in children (see [Figure 10](#)). Histological data can be useful in determining whether effects are occurring in the brain at lower fluoride concentrations; however, author descriptions of these effects may be limited thereby making it difficult to directly link histological changes in the brain to learning and memory effects. Oxidative stress is considered a general mechanistic endpoint that cannot be specifically linked to neurodevelopmental or cognitive effects in humans; however, like histopathology, it may help in identifying changes in the brain occurring at lower concentrations of fluoride. Although any effects in the brain or neurological tissue at lower concentrations of fluoride may support reduced IQ in humans, it may be difficult to distinguish the potential effects of fluoride on learning and memory functions from other neurological or general health outcomes.

Figure 9. Number of Animal Mechanistic Studies for Fluoride by Mechanistic Category and Exposure Level*

Mechanism	Dose Level	
	All	≤20 ppm
Biochemical (brain/neurons)	66	25
Neurotransmitters	53	23
Oxidative stress	78	25
Histopathology	67	30
Apoptosis/cell death	19	7
Inflammation	7	5
Thyroid	50	17
Other	3	2

*Interactive figure and additional study details in [Tableau®](#)

(https://public.tableau.com/profile/ntp.visuals#!/vizhome/Animal_Mechanisms_All_June2019/Figure8). The number of

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

studies that evaluated mechanistic effects associated with at least one exposure at or below 20 ppm fluoride is tabulated in the “≤20 ppm” column. The total number of studies per mechanistic category are summarized in the “All” column.

The following sections summarize the mechanistic data by category of mechanistic endpoint. Although there is some evidence of consistency in mechanistic effects, overall these data are insufficient to increase confidence or support a change to hazard conclusions.

Neurotransmitters

Twenty of 23 neurotransmitter studies assessed changes in brain cholinesterase activity associated with fluoride exposure at or below 20 ppm fluoride. Acetylcholine is a major neurotransmitter involved in learning, memory, and intelligence (Chen 2012, Gais and Schonauer 2017). AChE is responsible for the breakdown of acetylcholine in the synapses of nerve cells. Changes in cholinesterase, acetylcholine, or AChE could be related to effects on memory. Evidence of an effect varied among the lower risk-of-bias studies that assessed changes in cholinesterase or acetylcholine (n = 11 drinking water studies) (Gao *et al.* 2009, Baba *et al.* 2014, Adedara *et al.* 2017a, Khan *et al.* 2017, Gao *et al.* 2008a, Akinrinade *et al.* 2015a, Sun *et al.* 2000 [translated in Sun *et al.* 2008], Chouhan *et al.* 2010, Mesram *et al.* 2016, Liu *et al.* 2010, Nkpaa and Onyeso 2018), with the majority of studies reporting evidence of an effect that is considered inconsistent with the phenotypic outcome. Decreases in cholinesterase will cause increases in acetylcholine, which can have a positive effect on learning and memory; however, long-term decreases in cholinesterase can lead to secondary neuronal damage occurring in the cholinergic region of the brain (Chen 2012).

Five of the 11 studies with lower risk of bias (Gao *et al.* 2009, Baba *et al.* 2014, Adedara *et al.* 2017a, Khan *et al.* 2017, Nkpaa and Onyeso 2018) found statistically significant decreases in cholinesterase or AChE in brain homogenates (with some brains dissected into specific regions prior to homogenizing) with fluoride concentrations in drinking water at or below 20 ppm, and 4 of the 5 studies found statistically significant decreases in cholinesterase or AChE below 10 ppm. The 5 studies were conducted in rats (Wistar or Sprague-Dawley) with exposure ranging from 28 days to 6 months. An additional 2 out of 11 studies (Gao *et al.* 2008a, Akinrinade *et al.* 2015a) reported decreases in brain homogenate AChE at concentrations at or below 20 ppm fluoride in drinking water, but statistical significance was not reached. These studies were also conducted in rats with exposure for 30 days or 3 months. Gao *et al.* (2008a) reported a dose-dependent decrease in brain homogenate AChE in the low (5 ppm fluoride) and high (50 ppm fluoride) treatment groups compared with the control group, but the decrease was only statistically significant in the high dose group. Similarly, Akinrinade *et al.* (2015a) observed a dose-dependent decrease in percent intensity of AChE immunohistochemistry in the prefrontal cortex associated with 2.1 and 10 ppm sodium fluoride in the drinking water, but neither result was statistically significant. Gao *et al.* (2009) found lower brain homogenate AChE levels in the 5-ppm animals compared with the 50-ppm animals; therefore, the results were not always dose dependent.

Relative to the above-mentioned studies, 2 of the 11 lower risk-of-bias studies observed opposite effects on brain cholinesterase levels. Sun *et al.* (2000) [translated in Sun *et al.* 2008] observed a significant increase in brain cholinesterase in Kunming mice associated with fluoride drinking water concentrations from 10 to 100 mg/L, but did not observe a dose response. Chouhan *et al.* (2010) did observe a dose-related increase in AChE levels in brain homogenate of Wistar rats with sodium fluoride concentrations of 1 to 100 ppm for 12 weeks and noted statistically significant results at 1, 50, and 100 ppm but not at 10 ppm.

Mesram *et al.* (2016) did not assess changes in AChE but observed a significant decrease in acetylcholine levels in cerebral cortex homogenate through 30 days of age in rats treated in utero with 20 ppm

sodium fluoride, which may suggest an increase in AChE levels. Likewise, Liu *et al.* (2010) did not assess changes in AChE, but measured nicotinic acetylcholine receptors (nAChRs) in brain homogenate of rats following drinking water fluoride exposure, which the authors stated could modulate physiological and pharmacological functions that are involved in learning and memory-related behaviors. Significant decreases in the protein expressions of nAChR subunits at 2.26 ppm fluoride were observed; however, the corresponding receptor subunit mRNAs did not exhibit any changes (Liu *et al.* 2010).

The studies that assessed other neurotransmitters of the brain and neurons were too heterogeneous or limited in number to make any determination on mechanism, even before limiting the review of the data to lower risk-of-bias studies. There were only five studies that evaluated dopamine and/or metabolites (Tsunoda *et al.* 2005, Chouhan *et al.* 2010, Reddy *et al.* 2014, Banala *et al.* 2018, Sudhakar and Reddy 2018). Four of the studies observed decreases in dopamine levels in the brain with exposures less than 20 ppm fluoride (Reddy *et al.* 2014, Chouhan *et al.* 2010, Banala *et al.* 2018, Sudhakar and Reddy 2018); however, the fifth study (Tsunoda *et al.* 2005) observed increased dopamine and metabolites at fluoride exposures below 20 ppm (with statistical significance achieved only for the metabolite homovanillic acid in one brain region). No differences from the control group were observed at levels above 20 ppm fluoride. Other neurotransmitters were evaluated at or below 20 ppm fluoride exposure, but generally only in a couple of studies.

Biochemistry (brain/neurons)

Similar to above, the endpoints measured in brain biochemistry studies were too heterogeneous or limited in number to make any determination on potential relevance of mechanism, even before limiting the review of the data to lower risk-of-bias studies (see [Figure 10](#)). Endpoints related to biochemical changes in the brain or neurons included carbohydrate or lipid changes, RNA or DNA changes, changes in gene expression, or changes in protein expression. For the most part, only a single study was available for any given endpoint. The largest body of evidence on biochemistry was on protein level in various brain regions. Eleven lower risk-of-bias studies were identified that evaluated protein levels; however, few studies evaluated the same proteins or areas of the brain. In the few cases where the same protein was evaluated, results were not always consistent. These data are insufficient to increase confidence or support a change to hazard conclusions.

Histopathology

Histopathology of the brain was evaluated in 31 studies with concentrations at or below 20 ppm fluoride, of which 15 studies had a lower potential for bias (Adedara *et al.* 2017b, Akinrinade *et al.* 2015a, Bhatnagar *et al.* 2002, Bhatnagar *et al.* 2011, Chouhan *et al.* 2010, Guner *et al.* 2016, Jiang *et al.* 2014, Lou *et al.* 2013, McPherson *et al.* 2018, Mesram *et al.* 2016, Niu *et al.* 2018, Pulungan *et al.* 2016, Nageshwar *et al.* 2018, Zhao *et al.* 2019, Jia *et al.* 2019). In all but one lower risk-of-bias study [Pulungan *et al.* (2016); gavage], animals were exposed to fluoride via drinking water. All lower risk-of-bias studies were conducted in rodents, and all but three studies were conducted in rats (Wistar [seven studies]; Sprague-Dawley [four studies]; Long-Evans hooded [one study]). Overall, the lower risk-of-bias studies that evaluated histopathology in the brain had low potential for bias for key questions regarding randomization and exposure characterization; however, eight studies were rated as probably high risk of bias for the key risk-of-bias question regarding outcome assessment based on lack of reporting of blinding of outcome assessors and/or inadequate description of outcome measures or lesions. Moreover, low image quality in some of the studies hampered the ability to verify the quality of the data. Further technical review of the 15 lower risk-of-bias studies was conducted by a board-certified pathologist. Based on confidence in the results for each study, the technical reviewer further categorized the lower risk-of-bias studies as studies with higher or lower confidence in the outcome

assessment, which is reflected in the following summary of the brain histopathology results. Main limitations of the histopathology data identified by the pathologist included lack of information on methods of euthanasia and fixation. Perfusion fixation is generally considered the best practice for lesions of the central nervous system in addition to complete fixation of the brain prior to its removal from the skull (Garman *et al.* 2016). Four of the lower risk-of-bias studies reported that they used this method (Bhatnagar *et al.* 2002, Bhatnagar *et al.* 2011, McPherson *et al.* 2018, Pulungan *et al.* 2016). Two of the lower risk-of-bias studies handled the brains before fixation was complete, which can produce artifacts that can resemble dead neurons (Zhao *et al.* 2019, Nageshwar *et al.* 2018). Fixation and brain removal details were inadequately described in the remaining lower risk-of-bias studies.

Although there was heterogeneity in the endpoints reported (e.g., cell size, shape, and counts; nuclei fragmentation; increased vacuolar spaces) and some variation in the consistency of the evidence based on the area of the brain evaluated, the majority of the lower risk-of-bias studies (11 of 14 drinking water studies) found some histological change in the brain of rats or mice treated with fluoride at concentrations at or below 20 ppm, of which 8 studies reported histological changes in the brain at or below 10 ppm. Histological changes in the hippocampus (one of the areas of the brain most evaluated for histological changes) associated with fluoride exposures at or below 20 ppm were reported in three of four lower risk-of-bias studies with higher confidence in the outcome assessment (Bhatnagar *et al.* 2002, Bhatnagar *et al.* 2011, Guner *et al.* 2016) and in three of four lower risk-of-bias studies with lower confidence in the outcome assessment (Jiang *et al.* 2014, Niu *et al.* 2018, Nageshwar *et al.* 2018). McPherson *et al.* (2018) was the only drinking water study (with higher confidence in the histopathology outcome assessment) that did not observe any histological changes in hippocampus at 10 or 20 ppm fluoride in male Long-Evans hooded rats exposed in utero through adulthood (>PND80). Although there are too few studies to definitively explain the inconsistency in results, McPherson *et al.* (2018) also did not observe any associations between fluoride exposure and impairments to learning and memory, which is inconsistent with the majority of developmental exposure studies that observed learning and impairments associated with fluoride exposure for other strains of rats. Similarly, histological changes in the cortex were reported in three of the four lower risk-of-bias drinking water studies with higher confidence in the outcome assessment (Chouhan *et al.* 2010, Bhatnagar *et al.* 2011, Akinrinade *et al.* 2015a) and in three of four lower risk-of-bias studies with lower confidence in the outcome assessment (Lou *et al.* 2013, Mesram *et al.* 2016, Nageshwar *et al.* 2018).

Histological changes were also consistently reported in other areas of the brain in studies with higher confidence in the outcome assessment, including the amygdala, caudate putamen, cerebellum, and hypothalamus, although each of these areas of the brain were only evaluated in one lower risk-of-bias study (Bhatnagar *et al.* 2011, Guner *et al.* 2016). Pulungan *et al.* (2016), one of two lower risk-of-bias studies with higher confidence in the outcome assessment that did not report histological changes in the brain, observed a decreasing trend in the number of pyramidal cells in the prefrontal cortex with increasing dose, but this was not changed at concentrations below 20 ppm (study administered sodium fluoride via gavage; the 5-mg/kg-day dose was considered to be equivalent to 15.3 ppm fluoride in drinking water) nor were any of the results statistically significant.

Oxidative stress

Oxidative stress in the brain was evaluated in 25 studies that examined concentrations at or below 20 ppm fluoride, of which 15 studies had lower potential for bias (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Akinrinade *et al.* 2015b, Chouhan *et al.* 2010, Gao *et al.* 2008b, Guner *et al.* 2016, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Shan *et al.* 2004, Zhang *et al.* 2015a, Chouhan and Flora 2008, Gao *et al.* 2009, Khan *et al.* 2017, Bartos *et al.* 2018, Nageshwar *et al.* 2018). All of the lower risk-of-bias studies

were conducted in rats (mainly Wistar or Sprague-Dawley) and administered fluoride via drinking water with exposure durations ranging from 28 days to 7 months. Although there was heterogeneity in the endpoints reported (i.e., varying measures of protein oxidation, antioxidant activity, lipid peroxidation, and reactive oxygen species [ROS]) and some variation in the consistency of the evidence based on the endpoint, the majority of the studies (13 of 15 studies) (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Akinrinade *et al.* 2015b, Gao *et al.* 2008b, Gao *et al.* 2009, Guner *et al.* 2016, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Shan *et al.* 2004, Zhang *et al.* 2015a, Khan *et al.* 2017, Nageshwar *et al.* 2018, Bartos *et al.* 2018) found evidence of oxidative stress in the brains of rats treated with fluoride at concentrations at or below 20 ppm, of which 10 studies reported oxidative stress in the brain below 10 ppm fluoride. The most consistent evidence of oxidative stress in the brain was reported through changes in antioxidant activity. Eleven of the 12 lower risk-of-bias studies that evaluated antioxidant activity reported an effect at concentrations at or below 20 ppm (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Akinrinade *et al.* 2015b, Gao *et al.* 2008b, Gao *et al.* 2009, Guner *et al.* 2016, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Khan *et al.* 2017, Bartos *et al.* 2018, Nageshwar *et al.* 2018). Decreases in antioxidant activity using measures of superoxide dismutase (SOD) activity were reported in seven of eight lower risk-of-bias studies (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Akinrinade *et al.* 2015b, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Khan *et al.* 2017, Nageshwar *et al.* 2018) and, among these seven studies, all that also measured changes in catalase (CAT) activity (n = 6 studies) also reported decreased activity (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Khan *et al.* 2017, Nageshwar *et al.* 2018). A decrease in total antioxidant capacity (T-AOC) as a measure of antioxidant activity was also consistently reported in two lower risk-of-bias studies (Gao *et al.* 2008b, Gao *et al.* 2009), and a decrease in glutathione peroxidase (GPx) activity was reported in two of three lower risk-of-bias studies (Adedara *et al.* 2017b, Nkpaa and Onyeso 2018).

Relative to the above-mentioned studies, 2 of the 15 lower risk-of-bias studies (Chouhan and Flora 2008, Chouhan *et al.* 2010) did not observe statistically significant effects on oxidative stress in the brain with concentrations at or below 20 ppm fluoride; however, the measure of oxidative stress evaluated in Chouhan and Flora (2008) and Chouhan *et al.* (2010) (glutathione [GSH] to oxidized glutathione [GSSG] ratio as an indication of antioxidant activity and ROS levels) were not evaluated in any other lower risk-of-bias study. Chouhan and Flora (2008) observed a dose-dependent increase in ROS levels associated with 10, 50, and 100 mg/L sodium fluoride in the drinking water; however, results were not statistically significant at any dose. In Chouhan *et al.* (2010), the levels of ROS were significantly higher at 50 ppm sodium fluoride in drinking water, but statistical significance was not met at doses below 20 ppm fluoride (1 and 10 ppm sodium fluoride) or at 100 ppm sodium fluoride; yet, hydrogen peroxide levels as a measure of ROS were found to be significantly increased at 15 ppm sodium fluoride in drinking water in studies conducted by another group of authors (Adedara *et al.* 2017a, Adedara *et al.* 2017b).

Apoptosis/cell death

Seven lower risk-of-bias studies were identified that evaluated apoptosis with concentrations at or below 20 ppm fluoride. Results from these studies were inconsistent and were insufficient for evaluating fluoride-induced apoptosis. These data are insufficient to increase confidence or support a change to hazard conclusions.

Inflammation

Five lower risk-of-bias studies were identified that evaluated potential effects of fluoride on inflammation with concentrations at or below 20 ppm. The inflammation markers were too heterogeneous or limited in number to make any determination on potential relevance of mechanism,

even before limiting the review of the data to lower risk-of-bias studies. These data are insufficient to increase confidence or support a change to hazard conclusions.

Thyroid

Seventeen studies were identified that evaluated potential effects of fluoride on the thyroid with concentrations at or below 20 ppm (see [Figure 9](#)). These animal thyroid data are not further described because this endpoint has been directly evaluated in a number of human studies that have failed to identify consistent evidence to suggest that thyroid effects are a requisite mechanism by which fluoride causes neurodevelopmental or cognitive effects in humans.

Figure 10. Number of Lower Risk-of-bias Animal Studies that Evaluated Biochemical, Neurotransmission, and Oxidative Stress Effects at or Below 20 ppm by Mechanism Subcategory and Direction of Effect*

Mechanism	Mechanism Subcategory	Direction of Effect			Grand Total

*Interactive figure and additional study details in [Tableau®](#)

(https://public.tableau.com/profile/ntp.visuals#!/vizhome/Fluoride_Animal_SelectMechanisms_UPDATE/Figure9). This figure displays study counts for lower risk-of-bias studies, as these counts are most relevant to the text in this section. Counts for higher risk-of bias studies or all studies combined can be accessed in the interactive figure in [Tableau®](#). Study counts are tabulated by significance—statistically significant increase (↑), statistically significant decrease (↓), or not significant (NS). For example, the “↑” column displays numbers of unique studies with at least one endpoint in the mechanistic subcategory with significantly increasing results at fluoride exposure levels of ≤20 ppm. These columns are not mutually exclusive (i.e., a study may report on multiple endpoints with varying results within a single mechanistic subcategory and therefore may be reflected in the counts for the “↑”, “↓”, and NS columns, but would only be counted once in the Grand Total column). Endpoints, species, strain, sex, and exposure duration are available for each study in the interactive figure in [Tableau®](#).

In Vitro/Mechanistic Data on Neurodevelopmental or Cognitive Effects

Although in vitro data were collected as part of the systematic review process, NTP determined that the information on neurological effects obtained from these studies is too general, and results cannot necessarily be attributed to effects on learning and memory or other cognitive functions at this time. The in vitro data may help support specific mechanisms identified from in vivo mechanistic data; however, as described above, no specific mechanism has been determined for fluoride effects on learning and memory or other neurodevelopmental or cognitive outcomes.

Evidence Synthesis for Neurodevelopmental or Cognitive Effects

There is consistent evidence that exposure to fluoride is associated with cognitive neurodevelopmental effects in children. There is moderate confidence in the human data in children from 5 well-conducted

prospective studies, supported by 14 cross-sectional studies where exposure was identified as likely occurring prior to outcome. The human body of evidence in adults is considered inadequate to evaluate whether fluoride exposure is associated with cognitive effects due to low confidence in the human data in adults, a limited number of studies, and a lack of evidence of an effect (i.e., there is not sufficient evidence of an effect, but the confidence in the data is not high enough to conclude that there is no effect). The animal data are inadequate to evaluate for learning and memory effects primarily due to the uncertainty in distinguishing effects on cognitive outcomes from secondary effects on the nervous system or general health including motor activity issues; however, these data do provide evidence of other neurodevelopmental effects. There is also evidence from mechanistic studies of adverse neurological effects of fluoride in humans and animals of unknown relationship to cognition.

The initial moderate confidence is based on 19 studies where exposure occurred prior to outcome and that evaluated individual-based outcomes and used a comparison group. Factors considered for upgrading or downgrading the confidence are as follows:

- **Risk of bias:** Only studies that were considered to have lower risk of bias were included in the moderate confidence rating; therefore, there is no downgrade for risk-of-bias concerns.
- **Unexplained inconsistencies:** The data are relatively consistent and there was no downgrade for this factor. In terms of IQ data, 17 studies observed significant effects associated with fluoride, and 2 studies found no significant association but neither of these studies adjusted for confounders. Consistency among neurodevelopmental effects other than IQ was also considered; however, the conclusions are based on the IQ data so these other neurodevelopmental effects would not impact a potential adjustment in confidence. Studies measuring neurodevelopmental effects other than IQ did not show consistent effects. It is not known whether fluoride exposure would be expected to be associated with neurodevelopmental outcomes in addition to IQ or other cognitive measures.
- **Indirectness:** IQ in humans is a direct measure of effect and therefore no adjustment in confidence is warranted.
- **Imprecision:** The meta-analysis indicates that there was no reason to downgrade due to imprecision.
- **Publication bias:** While the meta-analysis that estimated the pooled SMD among 46 included studies (both higher and lower risk-of-bias) indicated that there was potential for publication bias, a subgroup analysis indicated that there was no publication bias among the lower risk-of-bias studies (see [Figure A5-8](#)). Among the higher risk-of-bias studies, the trim-and-fill analysis estimated that, in the absence of publication bias, the negative direction of effect and statistical significance remained ([Figure A5-9](#)). For the meta-analysis that calculated a pooled effect estimate among the studies with individual-level measures, the funnel plot indicated publication bias; however, the trim-and-fill analysis estimated that once adjusted for publication bias, the negative direction of effect remained ([Appendix 5, Figure A5-16](#) and [Figure A5-18](#)). Therefore, no downgrade was applied for publication bias.
- **Large magnitude of effect:** While some individual studies indicate a large magnitude of effect, the overall pooled effect estimate from the meta-analysis of studies with individual-level

measures does not demonstrate a large magnitude of effect ([Appendix 5](#)). Therefore, the overall data would not support an upgrade due to a large magnitude of effect.

- **Dose-response:** Linear dose-response models provide the best fit to the data in studies examining individual-level measures of fluoride exposure and IQ. A meta-analysis of studies that compared mean IQ scores between groups of children with different levels of fluoride exposure showed a significantly lower mean SMD at higher concentrations of fluoride (>1.5 mg/L) from water (SMD: -0.14; 95% CI: -0.19, -0.08; n = 31 studies) and urine (SMD: -0.18; 95% CI: -0.31, -0.05; n = 22 studies) ([Appendix 5](#)); however, the dose-response relationship at fluoride concentrations below 1.5 mg/L fluoride in urine or drinking water is less certain. The overall dose-response could be used to upgrade the confidence in the body of evidence.
- **Residual confounding:** Xiang *et al.* (2003a), Xiang *et al.* (2011), and Wang *et al.* (2012) studied the same population where arsenic occurred in the area with low fluoride, but did not occur in the area with high fluoride. This would have biased the results toward the null, but there was a significantly lower IQ scores in the area with high fluoride. The remaining studies do not provide enough information to consider residual confounding as an impactful factor for the body of evidence. Therefore, the overall data would not support an upgrade due to residual confounding.
- **Consistency:** There is consistent evidence across study populations and study designs that fluoride is associated with lower IQ scores at higher concentrations of fluoride. There is uncertainty and less of a consistent pattern at concentrations below 1.5 mg/L. There is also a lack of consistency observed with and among other types of neurodevelopmental effects. The consistency in the overall results of the data set could increase the confidence.

Summary judgement on potential upgrades or downgrades in the confidence: Although the OHAT approach for evidence integration allows for the initial confidence in the body of evidence to be increased based on consistency or dose response, the NTP judgement is that the magnitude of effect and the overall strength and quality of the human literature base provides a moderate confidence in the body of evidence that fluoride causes cognitive neurodevelopmental effects in children.

The moderate confidence in the body of evidence in children translates to a moderate level of evidence that fluoride is associated with lower IQ and other cognitive neurodevelopmental effects in children.

The limited and weaker evidence of cognitive effects in adults is considered to provide an inadequate level of evidence that fluoride is associated with cognitive effects in adults. The animal body of evidence is also considered to provide an inadequate level of evidence for cognitive effects in adults.

Integration of these level-of-evidence conclusions supports an initial hazard conclusion of *presumed to be a cognitive neurodevelopmental hazard to humans* because of the extent and consistency of effect in the available data in children. Because most of the available studies evaluated intelligence in children, the primary focus in human data was on IQ and other cognitive neurodevelopmental effects, which is the primary basis for the hazard conclusion. A separate conclusion on other neurodevelopmental effects was not reached based on limited information in humans.

The moderate level of evidence in the human data in children supports a hazard conclusion of *presumed* instead of *suspected* due to the relatively large and consistent body of evidence, especially in relation to measures of IQ (17 of 19 lower risk-of-bias studies that assessed IQ reported an association between

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

higher fluoride and lower IQ scores) across multiple populations. A conclusion of *presumed* is supported by a statistically significant effect observed in the meta-analysis. Furthermore, the *presumed* hazard conclusion is supported by the low expectation that new studies would decrease the hazard conclusion.

Effects in children

- **Human body of evidence:** Moderate Confidence = Moderate Level of Evidence
- **Animal body of evidence:** Overall poor quality of studies and few studies that specifically assess effects on learning and memory after exposure during developmental periods separately from other neurological effects including motor activity = Inadequate Level of Evidence
- **Initial hazard conclusion (Moderate Human x Inadequate Animal)** = Presumed to be a Cognitive Neurodevelopmental Hazard to Humans
- **Final hazard conclusion (after consideration of biological plausibility)** = Presumed to be a Cognitive Neurodevelopmental Hazard to Humans

Effects in adults

- **Human body of evidence:** Low Confidence with no discernible effect = Inadequate Level of Evidence
- **Animal body of evidence:** Overall poor quality of studies and few studies that specifically assess effects on learning and memory after exposure in adulthood separately from other neurological effects including motor activity = Inadequate Level of Evidence
- **Initial hazard conclusion (Inadequate Human x Inadequate Animal)** = Not classifiable
- **Final hazard conclusion (after consideration of biological plausibility)** = Not classifiable

DISCUSSION

The overall objective of this evaluation was to undertake a systematic review of published literature to reach conclusions concerning the potential for exposure to fluoride to affect neurodevelopment and cognition. This review only addresses whether exposure to fluoride could present a potential hazard (i.e., has the potential to cause harm at any exposure level, including exposures that are higher than typically encountered from consuming fluoridated drinking water in the United States). Benefits of fluoride with respect to oral health are not addressed in this monograph.

Given this context, when focusing on human epidemiology studies with exposures in ranges typically found in the water distribution systems in the United States (0.7 mg/L for optimally fluoridated community water systems)⁸ that can be evaluated for dose response, effects on cognitive neurodevelopment are inconsistent and therefore unclear. However, given the totality of the data, including studies with exposures to fluoride levels higher than the WHO safe water guideline of 1.5 mg/L in water (WHO 2011), the NTP concludes that fluoride is *presumed to be a cognitive neurodevelopmental hazard to humans*. This conclusion is based on a moderate level of evidence that shows a consistent and robust pattern of findings in human studies across several different populations demonstrating that higher fluoride exposure (e.g., >1.5 mg/L in drinking water) is associated with lower IQ and other cognitive effects in children. Limited and weaker evidence is considered to provide an inadequate level of evidence that fluoride is associated with cognitive effects in adults. The primary focus of the human data was on IQ and cognitive neurodevelopmental effects; therefore, the conclusion was based on these data. After further evaluation of the experimental animal data available in NTP (2016) and in this systematic review, NTP concludes that in terms of evaluating the effects of fluoride on learning and memory to support the cognitive effects observed in humans, the animal data are inadequate. The animal data do provide evidence for effects of fluoride on neurodevelopment; however, other neurodevelopmental outcomes were not further evaluated because of the limited information in humans. Biological plausibility of effects from mechanistic studies was considered but did not significantly influence the conclusions. Although multiple categories of mechanistic data were evaluated and provide some evidence of adverse effects in the brain, a coherent series of mechanistic events to account for fluoride-associated cognitive neurodevelopmental deficits is not sufficiently understood for these findings to contribute to the overall confidence assessment.

The human body of evidence provides a consistent and robust pattern of findings that higher fluoride exposure is associated with lower IQ scores in children. The moderate level of evidence is based on 5 lower risk-of-bias prospective cohort studies and 14 lower risk-of-bias cross-sectional studies that are considered to have sufficient evidence of fluoride exposure occurring prior to the outcome. The evaluation of the animal body of evidence in this assessment is an extension of the NTP (2016) systematic review on the association between fluoride exposure and neurobehavioral effects related to learning and memory in animals, which identified a concern related to indirectness. This concern was that many of the learning and memory tests rely on a motor response (e.g., latency to achieve the desired effect). The review of animal data published since the 2016 review focused on addressing this

⁸As of April 2020, 1.08% of persons living in the United States (~ 3.5 million people) were served by CWS containing ≥ 1.1 mg/L naturally occurring fluoride. CWS supplying water with ≥ 1.5 mg/L naturally occurring fluoride served 0.59% of the U.S. population (~ 1.9 million people), and systems supplying water with ≥ 2 mg/L naturally occurring fluoride served 0.31% of the U.S. population (~1 million people) (<https://www.cdc.gov/fluoridation/data-tools/reporting-system.html>).

indirectness concern. Further examination of the literature has not provided clarification of this issue. Due to the inability to separate these effects from effects on general health and other effects on the nervous system, the animal body of evidence is now considered inadequate to contribute to the evaluation of cognitive effects in humans. Although the animal data are not considered sufficient to specifically support the IQ changes observed in children, the data do support possible neurodevelopmental effects.

The NTP conclusion that fluoride is *presumed to be a cognitive neurodevelopmental hazard to humans* is supported by the extent, consistency, and robustness of the effect in the available data in children. Seventeen of the 19 lower risk-of-bias studies reported an association between higher fluoride exposure and lower IQ scores in children across multiple populations. Meta-analyses conducted at the recommendation of NASEM based on their review of the September 6, 2019 draft monograph provide further support for the hazard conclusion of *presumed* (NASEM 2020). The random-effects pooled SMD estimate from the 46 studies included in the group-level meta-analysis was consistent with two previous meta-analyses reporting statistically significant associations between higher fluoride exposure and lower IQ in children. A risk-of-bias subgroup analysis demonstrated that the significant negative association remained when the meta-analysis was restricted to 9 lower risk-of-bias studies. Further subgroup analyses by gender, age group, country, outcome assessment type, and exposure assessment type support a consistent and robust pattern of results. A second meta-analysis of the individual-level data from six lower risk-of-bias studies also provided evidence of a statistically significant negative association between fluoride exposure and lower IQ in children (overall pooled effect estimate per 1-mg/L increase in urinary fluoride was associated with a 1.40-point lower IQ score [95% CI: -2.33, -0.47]). Given the evidence, there is a low expectation that new studies would change the hazard conclusion.

There are few studies in humans and numerous studies in animals that evaluate mechanistic effects related to fluoride exposure. There are sufficient mechanistic data to determine that fluoride exposure at lower concentrations has effects on the nervous system; however, for the cognitive neurodevelopmental outcome evaluated, there are insufficient data to support a specific mechanism or mode of action. Due to the large number of mechanistic studies conducted in animals, evaluation of the mechanistic data in animals focused on studies that had exposures more relevant to humans (i.e., ≤ 20 ppm in the drinking water). Changes in AChE, which could potentially be related to cognitive effects such as IQ, were evaluated in one study of children and several studies of animals (measured in both the blood and in areas of the brain); however, the majority of these studies, including the study of children, reported results inconsistent with the phenotypic outcome. Animal studies that evaluated changes in other neurotransmitters and other biochemical measures provide some evidence of effects in the brain, but the data are limited due to the heterogeneity of the outcomes measured. Most consistently, studies evaluating histopathology and oxidative stress demonstrated that effects can occur in the brains of animals at or below 20 ppm, which, without supporting a specific mechanism or mode of action relevant to learning and memory impairments, provides evidence of an association between exposure to lower concentrations of fluoride and neurological effects in animals. Therefore, the evidence of neurological effects at exposure levels more relevant to humans that is demonstrated in the mechanistic data supports the NTP conclusion that fluoride is *presumed to be a cognitive neurodevelopmental hazard to humans*; however, it does not provide enough evidence to increase confidence in the human body of evidence or support a higher hazard identification conclusion.

Generalizability to the U.S. Population

For many years, fluoride concentrations were adjusted to levels between 0.8 and 1.2 mg/L in fluoridated community water systems in the United States. The U.S. Public Health Service recommended an adjustment downward to a fluoride concentration of 0.7 mg/L because of evidence of an increase in dental fluorosis in children (US DHHS 2015). In April 2020, the CDC Water Fluoridation Reporting System estimated that the majority (i.e., 97.5%) of fluoride concentrations in water for U.S. children and adolescents (≤ 19 years old) are below 1.2 mg/L (<https://www.cdc.gov/fluoridation/data-tools/reporting-system.html>).

NTP's conclusion that fluoride is *presumed to be a cognitive neurodevelopmental hazard to humans* is based on consistent evidence from 26 lower risk-of-bias studies that evaluated fluoride exposure and effects on children's IQ and other cognitive effects. Although there are many studies that evaluated associations between fluoride in the drinking water and IQ in children, no studies evaluating IQ were conducted in the United States. Generalizing the results from the IQ studies in this evaluation to the U.S. population can be difficult, in part because many studies were conducted in areas with fluoride drinking water concentrations that are much higher than drinking water fluoride concentrations in the United States. Among the human body of evidence evaluated for this assessment (including lower and higher risk-of-bias studies), there are 33 studies that evaluated associations between fluoride in drinking water and IQ in children and compared a reference or low exposure group to higher fluoride-exposed groups. Of these 33 studies, only 10 studies included fluoride exposure groups with fluoride concentrations < 1.5 mg/L (i.e., fluoride exposure groups that would potentially be relevant to levels observed in the United States) (Xu *et al.* 1994, Xiang *et al.* 2003a, Qin *et al.* 1990 [translated in Qin *et al.* 2008], Kang *et al.* 2011, Broadbent *et al.* 2015, Sebastian and Sunitha 2015, Sudhir *et al.* 2009, Zhang *et al.* 2015b, Zhang *et al.* 1998, Wang *et al.* 2020b). Of these 10 studies, 4 were considered to have lower risk of bias (Zhang *et al.* 2015b, Xiang *et al.* 2003a, Wang *et al.* 2020b, Sudhir *et al.* 2009).

In addition to the four studies mentioned above, several other studies that evaluated fluoride exposure on a continuous basis could be used to assess generalizability to the United States. This includes studies that examined fluoride exposure levels below 1.5 mg/L for which a dose response could be assessed. **Table 8** provides a summary of children's IQ studies that evaluated lower fluoride exposures (< 1.5 mg/L) in drinking water and/or urine (assuming, for comparison purposes, an approximate 1-to-1 equivalence between drinking water fluoride and urinary fluoride concentrations) and provided information to evaluate dose response in the lower fluoride exposure range (e.g., three or more fluoride exposure groups or dose-response curve provided). Based on review of these studies (discussed further below), there is uncertainty if IQ changes in children occur at lower fluoride levels.

Among studies with lower risk of bias for which a dose response could be assessed, four of nine studies that examined fluoride exposure levels below 1.5 mg/L (**Table 8**) (Green *et al.* 2019, Zhang *et al.* 2015b, Xiang *et al.* 2003a, Wang *et al.* 2020b) applied regression models to individual exposure outcome measures and observed a linear association between urinary fluoride levels and lower IQ in children even at the lower fluoride concentrations. However, two of these studies (Xiang *et al.* 2003a, Zhang *et al.* 2015b) did not find an association between IQ and drinking water levels below 1.5 mg/L. Xiang *et al.* (2003a) observed a significantly lower IQ in endemic versus nonendemic villages, but when they grouped children from the endemic villages by exposure level, they did not observe a significantly lower IQ score for children exposed to lower mean exposure levels of fluoride (0.75 mg/L). Although a significant difference in IQ might not be expected due to the fact that there were only nine children in this group, the difference was less than one point in IQ. Zhang *et al.* (2015b) used a simple correlation

and did not observe a significant relationship between fluoride levels in the drinking water (with concentrations up to 1.57 mg/L) and IQ. Sudhir *et al.* (2009) observed a significant increase in IQ grade (which is associated with lower IQ) at concentrations of 0.7–1.2 mg/L. The other four of nine studies do not provide a clear dose response at the lower fluoride levels. Bashash *et al.* (2017) concluded that there was no clear association between IQ scores and maternal urinary fluoride below 0.8 mg/L. Yu *et al.* (2018) observed a correlation between lower IQ in children and fluoride exposure only with concentrations in drinking water above 3.4 mg/L or with urinary fluoride concentrations of 1.6 mg/L or higher. The study authors did note a decreased probability of having an IQ above 130 (i.e., 40% fewer people with high IQ for every 0.5-mg/L increase in fluoride) with water fluoride levels between 0.20 and 1.40 mg/L, but this was not observed with higher levels of fluoride. Although Cui *et al.* (2018) noted that IQ decreased in a “roughly linear manner” with increasing urinary fluoride, this is only apparent in the results for the TT genotype; based on the dose response, the authors concluded that the “safety threshold” was 1.73 mg/L. Ding *et al.* (2011) looked at mean differences for 10 different exposure groups and found notable decreases from the mean above approximately 1 mg/L.

Although there is less confidence in the findings from higher risk-of-bias studies, six studies identified with potential dose-response information demonstrated a similar uncertainty at the lower fluoride concentrations. Surprisingly, three of the studies (Aravind *et al.* 2016, Qin *et al.* 1990 [translated in Qin *et al.* 2008], Xu *et al.* 1994) found that the lowest IQ scores were in areas with the lowest and the highest fluoride concentrations. In these studies, the lowest fluoride concentrations ranged from 0.1–0.2 mg/L fluoride in Qin *et al.* (1990) [translated in Qin *et al.* 2008] to <1.2 mg/L in Aravind *et al.* (2016). Li *et al.* (1995) and Sebastian and Sunitha (2015) only observed lower IQ scores at concentrations above 2 mg/L. Das and Mondal (2016) found a steady decline in IQ with increasing urinary fluoride levels or exposure dose.

To further examine the dose response for lower IQ in the lower exposure region (e.g., <1.5 mg/L fluoride in drinking water or urine), a meta-analysis ([Appendix 5](#)) using a linear mixed model to analyze mean-effect estimates was performed. Twelve observations from 9 studies were included that reported one or more IQ measurements associated with drinking water fluoride exposures of < 1.5 mg/L and a reference group. This analysis did not show a statistically significant association with the mean SMD in children’s IQ scores between exposed and reference groups (SMD = 0.32; 95% CI: –0.57, 1.20). A dose-response meta-analysis including seven observations from four studies with at least one exposure group < 1.5 mg/L urinary fluoride showed a non-statistically significant decrease in mean SMD (SMD = –0.13; 95% CI: –0.29, 0.03). Based on these results, effects of fluoride exposure on children’s IQ at levels < 1.5 mg/L remain unclear and more studies at lower exposure levels are needed. A dose-response meta-analysis of studies with individual-level data could not be conducted due to the small number of studies (n = 10), the various types of exposure metrics, and the different types of reported effect estimates. More studies with lower levels of fluoride exposure from drinking water are still needed to fully understand potential effects at exposures in ranges typically found in the United States (i.e., <1.5 mg/L). Of note, the negative association between IQ and fluoride exposure via drinking water was statistically significant when extending the dose-response meta-analysis to include IQ measures from groups exposed to <2 mg/L in drinking water (SMD = –0.27; 95% CI: –0.36, –0.17). A statistically significant decrease in mean SMD in children’s IQ scores was not seen in urinary fluoride measures of < 2 mg/L (SMD = –0.09; 95% CI: –0.22, 0.03) ([Table A5-3](#)).

When generalizing findings from the cited studies to exposures in the United States from fluoride in drinking water, it is important to consider that drinking water only comprises a portion of total exposures to fluoride. Although it can be assumed that children in all the studies cited in this document

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

are also exposed to fluoride from sources other than drinking water, these other exposures are likely to vary considerably depending on individual circumstances. Fluoride concentrations in drinking water alone do not reflect the magnitude of fluoride exposures to children who consume excessive amounts of fluoridated toothpaste or to formula-fed babies who consume powdered formula that is reconstituted with fluoridated water. A few studies also support the possibility of heightened sensitivities to the detrimental cognitive effects of fluoride exposures in individuals with certain polymorphisms in dopamine receptor D2, or catechol-O-methyltransferase (Cui *et al.* 2018, Zhang *et al.* 2015b), impacting dopamine catabolism and receptor sensitivity. Differential exposures to fluoride and genetic susceptibilities of children to fluoride appear to warrant further research.

Table 8. Human Studies with Lower Fluoride Exposure and Effects on IQ		
Study	Exposure measures [mean $\pm$ SD (range)]	Notes
Lower risk-of-bias studies		
Bashash <i>et al.</i> (2017)	Maternal urine during pregnancy (mg/L) 0.90 $\pm$ 0.35 (0.23–2.36)	Authors concluded that the model suggested a nonlinear relationship with no clear association between IQ scores and maternal urine below 0.8 mg/L.
	Children’s urine (mg/L) 0.82 $\pm$ 0.38 (0.18–2.8)	
Green <i>et al.</i> (2019)	Maternal urine during pregnancy (mg/L) 0.51 $\pm$ 0.36 (0.06–2.44) 0.40 $\pm$ 0.27 non-fluoridated areas 0.69 $\pm$ 0.42 fluoridated areas	Statistical methods indicated that including quadratic or natural-log effects of maternal urine or intake did not significantly improve the model. In addition, the authors tested separate models with two linear splines to see if the effect of maternal urinary fluoride or maternal fluoride intake significantly differed between lower and higher levels based on knots set at 0.5, 0.8, and 1.0 mg/L for urine and 0.4, 0.8, and 1 mg for intake. There were no differences.
	Maternal intake during pregnancy (mg/day) 0.54 $\pm$ 0.44 (0.01–2.65) 0.30 $\pm$ 0.26 non-fluoridated areas 0.93 $\pm$ 0.43 fluoridated areas	
	Drinking water (mg/L)* 0.31 $\pm$ 0.23 (0.04–0.87 ¹) 0.13 $\pm$ 0.06 non-fluoridated areas 0.59 $\pm$ 0.08 fluoridated areas	
Cui <i>et al.</i> (2018)	Drinking water (mg/L)* 0.20–1.00 non-endemic 1.52–2.49 endemic	Study authors noted that the IQ decreased in a “roughly linear manner as the log-urine fluoride increased.” TT genotypes of the dopamine receptor D2 gene had the strongest negative correlation between log-urine fluoride and IQ scores. The study authors determined a safety threshold of urine fluoride levels in subgroup TT as 1.73 mg/L. Drinking water fluoride levels were used to select children from different areas but were not used in the analysis.
	Children’s urine Levels not provided; log-transformed with range of approximately –1.2–2.2	
Ding <i>et al.</i> (2011)	Drinking water (mg/L) * 1.31 $\pm$ 1.05 (0.24–2.84)	Although there was a significant correlation between urinary fluoride and IQ score, the main drop in IQ occurred at urinary fluoride levels of approximately 0.7–1.2 mg/L. At levels below 0.7 mg/L, data suggest a plateau with no apparent change in IQ compared with the mean. Drinking water fluoride levels were not used in the analysis.
	Children’s urine (mg/L) 0.10–3.55	

Table 8. Human Studies with Lower Fluoride Exposure and Effects on IQ		
Study	Exposure measures [mean $\pm$ SD (range)]	Notes
Sudhir <i>et al.</i> (2009)	Drinking water (mg/L)* <0.7 (level 1 villages) 0.7–1.2 (level 2 villages) 1.3–4.0 (level 3 villages) >4.0 (level 4 villages)	The number of intellectually impaired children gradually increased with increasing fluoride concentration in drinking water with an increase in IQ grade (which indicates a decrease in IQ) observed in the 0.7–1.2-mg/L villages. Children were placed in exposure groups based on Water Works Department records. Although children brought in water for verification of strata, it was not collected from all children but only from the first child using a different source of water. Therefore, these are considered group-level data. Note that all groups had a large proportion in the “intellectually impaired” category.
Wang <i>et al.</i> (2020b)	Drinking water (mg/L)* 1.39 $\pm$ 1.01 (0.20–3.90)	There was a significantly lower IQ in quartile 3 (1.00–1.90 mg/L) and quartile 4 (>1.90 mg/L), but not quartile 2 (0.70–1.00 mg/L) of drinking water. Urinary fluoride was only associated with a significantly lower IQ in quartile 4 (>2.28 mg/L).
	Children’s urine (mg/L) 1.28 $\pm$ 1.30 (0.01–5.54)	
Xiang <i>et al.</i> (2003a)	Drinking water (mg/L)* 0.36 $\pm$ 0.15 (0.18–0.76) non-endemic village 2.47 $\pm$ 0.79 (0.57–4.50) endemic village Endemic subgroups: group A: 0.75 $\pm$ 0.14 group B: 1.53 $\pm$ 0.27 group C: 2.46 $\pm$ 0.30 group D: 3.28 $\pm$ 0.25 group E: 4.16 $\pm$ 0.22	IQ in group A in the endemic village was not significantly lower than the non-endemic village, but IQ in all other groups was significantly lower. Although there were only 9 children in group A, the IQ difference was <1 point. Based on simple regression, there was a steady decline in IQ with increasing urinary fluoride.
	Children’s urine (mg/L) 1.11 $\pm$ 0.39 (0.37–2.50) non-endemic village 3.47 $\pm$ 1.95 (0.90–12.50) endemic village	
Yu <i>et al.</i> (2018)	Drinking water (mg/L)* 0.50 $\pm$ 0.27 normal 2.00 $\pm$ 0.75 high	Study authors reported that participants' intelligence presented inverse non-linear dose-response relationships with fluoride content, with obvious decreases at relatively high level of fluoride exposure (drinking water fluoride levels at 3.4–3.90 mg/L and urinary fluoride levels at 1.60–2.50 mg/L). Study authors also note a decreased odds for having IQ $\geq$ 130 with drinking water fluoride at 0.20–1.40 mg/L (40% decrease with each 0.5-mg/L increase in fluoride), but not at higher concentrations.
	Children’s urine (mg/L) 0.41 $\pm$ 0.49 normal 1.37 $\pm$ 1.08 high	

Table 8. Human Studies with Lower Fluoride Exposure and Effects on IQ		
Study	Exposure measures [mean ± SD (range)]	Notes
Zhang <i>et al.</i> (2015b)	Drinking water (mg/L)* 0.63 (0.58–0.68) control 1.40 (1.23–1.57) endemic fluorosis	There was a steady decline in IQ with increasing serum or urinary fluoride levels. A simple correlation did not find drinking water fluoride significantly correlated with IQ.
	Children’s urine (mg/L) 1.1 ± 0.67 control 2.4 ± 1.01 endemic fluorosis	
	Children’s serum (mg/L) 0.06 ± 0.03 control 0.18 ± 0.11 endemic fluorosis	
Higher risk-of-bias studies		
Aravind <i>et al.</i> (2016)	Drinking water (mg/L)* <1.2 low fluoride area 1.2–2 medium fluoride area >2 high fluoride area	Mean IQ scores (transformed into percentiles) were highest in the medium fluoride area for both boys and girls.
Das and Mondal (2016)	Groundwater (mg/L)* 2.11 ± 1.64 (0.25–9.40)	Based on simple regression, there was a steady decline in IQ with increasing urinary fluoride and increasing exposure dose.
	Children’s urine (mg/L) 0.45–17.00	Groundwater fluoride levels were not used in the analysis but were used in calculating the children’s exposure dose.
	Children’s exposure dose (mg/kg-day) 0.017–0.203	
Li <i>et al.</i> (1995)	Children’s urine (mg/L) 1.02 non-fluorosis area 1.81 slight fluorosis area 2.01 medium fluorosis area 2.69 severe fluorosis area	A significantly lower IQ score was observed in the medium and severe fluorosis areas compared to the non-fluorosis area. Children’s urine was used as an individual measure of exposure to verify that the areas had different fluoride exposure levels; however, analysis was conducted based on residential area.
Qin <i>et al.</i> (1990) [translated in Qin <i>et al.</i> 2008]	Drinking water (mg/L)* 0.1–0.2 low fluoride area 0.5–1.0 normal fluoride area 2.1–4.0 high fluoride area	Average IQ scores (transformed into percentages) were significantly lower in both the low and high fluoride areas compared with the normal fluoride area.
Sebastian and Sunitha (2015)	Drinking water (mg/L)* 0.40 (low fluoride village) 1.2 (normal fluoride village) 2.0 (high fluoride village)	A significantly lower mean IQ score of children living in the high fluoride area compared with the low and normal fluoride areas was reported. Binary regression models using the low fluoride village as a reference observed an increased odds ratio (1.74) for increased IQ scores in the normal fluoride village and a decreased odds ratio (0.59) in the high fluoride village.
Xu <i>et al.</i> (1994)	Drinking water (mg/L)* 0.8 (control area) 0.38 (low fluoride area) 1.8 (high fluoride area)	Both low and high fluoride areas had IQ levels approximately 3 points below the IQ levels in the control area. There was no difference in IQ between the low and high fluoride areas.

*Data are group-level exposure data; exposure data without the asterisks are individual-level exposure data.

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

¹Range data were obtained from Till *et al.* (2018).

The conclusion that fluoride is *presumed to be a cognitive neurodevelopmental hazard in children* is based on the consistency of the data; however, most lower risk-of-bias studies observed effects with drinking water concentrations above 1.5 mg/L. As noted above, describing the effects at 1.5 mg/L or below, which is more relevant to the exposures observed in the U.S. population, including from community water fluoridation, is more difficult. In the reviewed studies, when limiting studies to those that evaluated IQ at fluoride levels across a continuum that included the low dose range, results are less consistent.

Limitations of the Evidence Base

Few limitations exist in the lower risk-of-bias epidemiological studies used for the basis of the hazard conclusion. The main limitations in lower risk-of-bias epidemiological studies include:

- Few studies were available that assessed the association between fluoride exposure and the following:
 - Neurodevelopmental or cognitive effects in subjects from communities served by optimally fluoridated versus non-fluoridated water systems.
 - Neurobehavioral (i.e., cognitive) effects (particularly IQ) in adults.
 - Attention-related disorders including ADHD.
- Studies rarely separated the results by gender or provided information to indicate that gender was not a modifying factor, which limits the ability to evaluate how the association between fluoride exposure and cognitive neurodevelopmental effects in children might differ by gender.

Limitations in the epidemiological studies with higher risk of bias include:

- Many of the original publications were in a foreign language and provided limited details on methodology.
- Some studies lacked information regarding exposure and/or had serious limitations in the exposure assessment. Exposure assessment concerns include limited individual exposure information, a lack of information on fluoride sampling methods and timing of the exposure measurements, a lack of quantitation of levels of fluoride in drinking water, and a lack of individual-level information on fluorosis in areas reported to be endemic for fluorosis.
- The comparison groups in studies conducted in areas endemic for fluorosis may have still been exposed to high levels of fluoride or levels similar to those used in water fluoridation in the United States. This factor may have limited the ability to detect true effects.
- Most studies did not provide sufficient direct information (e.g., participation rates) to evaluate selection bias.
- Failure to address potential confounders was a main issue. Many studies conducted simple statistical analyses without accounting for any potential confounders. In cases where adjustments in analyses were made, often these studies did not account for potential confounders considered critical for that study population and outcome.

This DRAFT Monograph is distributed solely for the purpose of pre-dissemination peer review and does not represent and should not be construed to represent any NTP determination or policy.

- Studies conducted in areas with high, naturally-occurring fluoride levels in drinking water often did not account for potential exposures to arsenic or iodine deficiencies in study subjects.
- Many studies did not account for potential exposures to lead as a residual confounder.
- Many studies lacked information on whether the outcome assessors were blind to the exposure group, including studies that examined children in their schools and subjects from high-fluoride communities.

Limitations in the animal studies include:

- The main limitation in the animal studies was the inability to separate possible learning and memory effects from effects on motor activity/coordination or sensory effects.
- Few learning and memory studies in animals evaluated motor activity or sensory effects. Studies that did evaluate motor activity or sensory effects often lacked discussion on general health of the animals when the endpoints measured could be affected by deficits in motor activity or sensory, such as latency to achieve a desired result.

A key data gap in the human and animal bodies of evidence includes the need for mechanistic insight into fluoride-related neurodevelopmental or cognitive changes.

Limitations of the Systematic Review

There are no major limitations of the systematic review. The human body of evidence included a large database of observational studies. Most of the observational studies were cross-sectional; however, nine of these were considered to be functionally prospective in nature. In addition, the systematic review covered a wide range of study designs, populations, and measures of fluoride exposure. The systematic review was designed to cover reports on all potential mechanistic data including effects on the thyroid. After review of the studies evaluating thyroid effects, studies that only evaluated goiters and other effects on thyroid size were not considered in this review. This is not considered a limitation because changes in thyroid size are not functional changes to the thyroid that could specifically indicate a mechanism for thyroid involvement in neurodevelopment. In addition, review of the mechanistic data was limited to in vivo studies with at least one concentration below 20 ppm. This is not considered a limitation for the systematic review since the mechanistic body of evidence was used to evaluate biological plausibility for the effects observed in humans; therefore, data were limited to concentrations that would be more reflective of human exposures. The decision to not more closely evaluate the in vitro data is not considered a limitation because there were sufficient in vivo data, and no key events were identified where in vitro data would provide additional insight.

CONCLUSION

Because the majority of available studies evaluated cognitive neurodevelopmental effects in children, the focus of the hazard conclusions is on cognitive neurodevelopmental effects, primarily IQ. When focusing on findings from studies with exposures in ranges typically found in drinking water in the
